VNIVERSITAT D VALÈNCIA

Doctorado en Biomedicina y Farmacia

**Advanced Systems for Skin Delivery of
Cyanocobalamin: A Model Molecule for > 1
kDa Drugs**

Tesis Doctoral presentada por:

Antonio José Guillot García

Directoras de la tesis:

Dra. Ana Melero Zaera

Dra. Teresa M^a Garrigues Pelufo

Valencia, 2022

VNIVERSITAT D VALÈNCIA

Doctorado en Biomedicina y Farmacia

Ana Melero Zaera, Doctora en Farmacia, Profesora Titular de Universidad del Departamento de Farmacia y Tecnología Farmacéutica y Parasitología de la Universidad de Valencia, y **Teresa M^a Garrigues Pelufo**, Doctora en Farmacia, Catedrática de Universidad del Departamento de Farmacia y Tecnología Farmacéutica de la universidad de Valencia,

CERTIFICAN:

Que el trabajo presentado por el Gdo. en Farmacia **Antonio José Guillot García**, titulado “**Advanced Systems for Skin Delivery of Cyanocobalamin: A Model Molecule for > 1 kDa Drugs**”, para obtener el grado de Doctor con mención internacional, ha sido realizada bajo nuestra dirección y asesoramiento.

Concluido el trabajo experimental y bibliográfico, autorizamos la presentación de la Tesis, para que sea jugado por el tribunal correspondiente. Para que conste, firman el presente documento, en Valencia a 6 de junio de 2022.

Ana Melero Zaera

Teresa M^a Garrigues Pelufo

7th February 2022

To Whom it May Concern

I certify that Antonio José Guillot García, with Spanish Passport number PAF384877, was at the Leicester School of Pharmacy at De Montfort University for his research stay, from the 13th September to 13th December 2021.

Antonio worked on the research project “Liposome-loaded microneedles for topical drug delivery”, under the supervision of Dr. Ana Sara Cordeiro, Senior Lecturer in Pharmaceutical Sciences.

Yours sincerely

A handwritten signature in blue ink, appearing to read "Antony D'Emanuele", written in a cursive style.

Antony D'Emanuele BPharm PhD MRPharmS CChem FRSC

Professor of Pharmaceutics and Head of the Leicester School of Pharmacy

This work has been funded by the following grants:

- “Atracció de Talent” fellowship of the university of Valencia (No. UV-INV-PREDOC-18F2-743816).
- University of Valencia 2019 grant (No. UV-19-INV-AE19).
- “Proyecto Emergente” from Conselleria d’Educació, Cultura i Esport (No. GV2015-054).
- This thesis is part of the grant PID2020-114530GA-I00 funded by MCIN/AEI/10.13039/501100011033.

Agradecimientos

Agradecimientos

Todo lo que tiene un principio, tiene un fin. Y en ocasiones hay finales que, aun siendo conocidos con antelación, son difíciles de gestionar. Entre otras cosas, por saber que hay muchas personas que te han ayudado a llegar hasta este momento y resulta imposible agradecer directamente su contribución. Por tanto, todo aquel que sea olvidado a lo largo de estas líneas, pero sienta que un trozo de esta tesis es suyo, mis más sinceras disculpas.

En primer lugar, a mis directoras. Mi eterno agradecimiento a Ana, por creer siempre en mí, su guía científica, pero, sobre todo, por su preocupación e influencia a nivel personal. A Teresa, por su personalidad y entusiasmo arrollador, que han permitido mejorar constantemente el trabajo realizado.

A Sara, por dejarme entrar en su laboratorio, confianza y, literalmente, permitirme campar a mis anchas. Sin duda, la estancia ha sido una de las paradas más valiosas de este viaje. A las profesoras M^a Carmen Montesinos, Rosa Giner y M^a Carmen Recio, por el empuje farmacológico final de esta tesis. A la Universidad de Valencia por su mecenazgo y posibilitar que, mediante la beca "Atracció de Talent", unos estudios se convirtieran en un trabajo. Lo siguiente que se me viene a la cabeza son, inevitablemente, mis amigos de la carrera. Aunque creo que siempre tuve bastante claro que este era mi camino, los momentos duros han sido mucho más llevaderos gracias a Pablo, Ausias, Tesa, Ana, Esther, David, Borja y Chema. Por extensión, a mis compañeros del máster, Asun, Josep, Silvia, Arturo, Lucía y Gabriela. Por vuestra amistad y por ese primer año de clases, prácticas y días de laboratorio que acababan con un denominador común, en un antro a altas horas de la madrugada y muchas cervezas sobre la mesa. Tampoco puedo olvidarme de los neurocientíficos del laboratorio de al lado, Javi, Jesús, Sandra y Claudia, porque me han hecho sentir uno más de ellos.

A mi madre y mi tía, por su apoyo y comprensión, aunque muchas veces no entendieran nada sobre lo que les estaba hablando. Por último, a quienes el recuerdo mantiene vivos, mis abuelos, porque gracias a su esfuerzo permitieron a los que vinimos detrás poder vivir tranquilos y dedicarnos a aquello que más nos interesa, sin tener que preocuparnos por nada más.

Resumen

1. Introducción	I

3.1.5.3. Industrial methods	42
3.1.6. Drug-loading strategies	42
3.1.6. Key properties and parameters in the design of lipid vesicles for transdermal delivery purposes	43

3.1.6.1. Entrapment efficiency	44
3.1.6.2. Determination of phospholipid concentration	45
3.1.6.3. Size and morphology	46
3.1.6.4. Polydispersity index	50
3.1.6.5. Vesicle flexibility.....	50
3.1.6.6. Drug release	51
3.1.6.7. Stability	53
3.1.6.8. Biocompatibility	61
3.2. Microneedle arrays.....	64
3.2.1. Microneedle-based transdermal delivery approaches	65
3.2.1.1. Solid MNA for “poke and patch”	65
3.2.1.2. Coated MNA for “coat and poke”	66
3.2.1.3. Dissolving and hydrogel-forming MNA for “poke and release”	67
3.2.1.4. Hollow MNA for “poke and flow”	69
3.2.2. MNA fabrication: materials and manufacturing processes.....	69
3.2.3. Safety considerations	71
3.2.3.1. Pain.....	71
3.2.3.2. Infections.....	72
3.2.3.3. Biocompatibility, immunogenicity, and local skin reactions..	73
 <u>Chapter 4. Development and validation of an analytical method for cyanocobalamin</u>	
4.1. Materials and methods	75
4.1.1. Materials	75
4.1.2. Equipment.....	75
4.1.3. Stationary phase and mobile phase	75
4.1.4. Analytical conditions	75
4.1.5. Validation of the analytical method.....	76
4.2. Results and Discussion.....	77
4.3. Milestone and highlights of chapter 4.....	81

Chapter 5. Design, development, and characterisation of cyanocobalamin lipid vesicles

5.1. Materials and methods	82
5.1.1. Materials	82
5.1.2. Methods	83
5.1.2.1. Preparation of liposomes, transfersomes and ethosomes ...	83
5.1.2.2. Determination of particle size, PDI and zeta-potential	86
5.1.2.3. Determination of phospholipid content of vesicles	86
5.1.2.4. Determination of the entrapment efficiency	87
5.1.2.5. Differential scanning calorimetry	87
5.1.2.6. Evaluation of lipid vesicle flexibility	87
5.1.2.7. Vesicle morphology: TEM imaging	88
5.1.2.8. Stability studies	88
5.1.2.9. Freeze-drying	88
5.1.2.10. Thermogravimetric assay	89
5.1.2.11. Drug release study and kinetic model fitting	89
5.1.2.12. Cellular biocompatibility	91
5.1.2.13. Statistical analysis	92
5.2. Results and Discussion	93
5.2.1. Particle size, PDI, zeta potential and phospholipid content	93
5.2.2. Entrapment efficiency	96
5.2.3. Vesicle morphology: TEM imaging	100
5.2.4. Evaluation of lipid vesicle flexibility	102
5.2.5. Stability studies	103
5.2.5.1. Short-term stability	103
5.2.5.1. Long-term stability	105
5.2.6. Freeze-drying	107
5.2.7. Thermogravimetric analysis	111
5.2.8. Differential scanning calorimetry	112
5.2.9. Drug release study	116
5.2.10. Kinetic model fitting	118
5.2.11. Cellular biocompatibility	119

5.3. Milestone and highlights of chapter 5.....	121

Chapter 6. Design, development, and characterisation of cyanocobalamin dissolving microneedle arrays

6.1. Materials and methods	123
6.1.1. Materials	123
6.1.2. Methods	123
6.1.2.1. Preparation of cyanocobalamin dissolving MNA.....	123
6.1.2.2. Microneedle morphology: SEM imaging.....	125
6.1.2.3. Mechanical strength and insertion properties of MNA	125
6.1.2.4. Thermogravimetric analysis.....	126
6.1.2.5. Differential scanning calorimetry	127
6.1.2.6. Drug release study and kinetic model fitting.....	127
6.1.2.7. Statistical analysis	128
6.2. Results and Discussion.....	129
6.2.1. Preparation of cyanocobalamin dissolving MNA.....	129
6.2.1.1. Thermogravimetric analysis.....	130
6.2.1.2. Differential scanning calorimetry	132
6.2.2. Microneedle morphology: optical microscopy and SEM	134
6.2.3. Mechanical strength and insertion properties of MNA	137
6.2.4. Drug release study and kinetic model fitting	141
6.3. Milestone and highlights of chapter 6.....	143

Chapter 7. Ex vivo and in vitro evaluation of cyanocobalamin penetration and permeability from lipid vesicles and dissolving microneedle arrays

7.1. Materials and methods	144
7.1.1. Materials	144
7.1.2. Methods	144
7.1.2.1. Drug distribution within skin layers and stratum corneum depth	144
7.1.2.2. In vitro drug permeability through the skin	145
7.1.2.3. Visualisation of micro-pores created by solid MNA.....	146

7.1.2.4. Statistical analysis	146
7.2. Results and discussion	147
7.2.1. Drug distribution within skin layers and <i>stratum corneum</i> depth	147
7.2.2. <i>In vitro</i> drug permeability through the skin from lipid vesicles ..	151
7.2.3. Visualisation of micro-pores created by solid MNA.....	157
7.2.4. <i>In vitro</i> drug absorption through the skin from dissolving MNA	158
7.3. Milestone and highlights of chapter 7.....	163

Chapter 8. Evaluation of cyanocobalamin lipid vesicles in a murine model of contact dermatitis

8.1. Materials and methods	165
8.1.1. Materials	165
8.1.2. Methods	165
8.1.2.1. Animals and housing conditions	165
8.1.2.2. Induction of DTH and evaluation of the ear oedema.....	166
8.1.2.3. Bioluminescence imaging.....	167
8.1.2.4. Histopathological study.....	167
8.1.2.5. Statistical analysis	168
8.2. Results and Discussion.....	168
8.2.1. Induction of DTH and evaluation of the ear oedema	168
8.2.2. Bioluminescence imaging.....	170
8.2.3. Histopathological study.....	172
8.3. Milestone and highlights of chapter 8.....	174

Resumen

1. Introducción

La piel ofrece una vía muy atractiva para la administración de fármacos por varias razones. En primer lugar, presenta varias ventajas sobre las principales vías de administración, como la oral o la parenteral. La administración transdérmica de fármacos tiene una buena aceptación y cumplimiento por parte de los pacientes, suele ser indolora y no necesita condiciones de asepsia y personal médico especializado para su administración. En segundo lugar, su gran superficie -aproximadamente 20.000 cm² en individuos adultos- la convierten en la mayor vía de entrada de sustancias exógenas al organismo. Por último, las dosis de fármaco administradas se pueden reducir, ya que se evita el primer paso hepático y degradación a nivel gástrico, evitando diversos efectos secundarios o adversos no deseados. Además, otras rutas alternativas como las mucosas sublingual, bucal y rectal son más erráticas y presentan limitaciones.

1.1. Administración tópica de fármacos

El proceso de absorción de fármacos a través de la piel está, claramente influido por las propiedades de la molécula bajo estudio, lo que condiciona en gran medida la posibilidad de administración tópica o transdérmica. En este sentido, se han definido como características ideales para que un fármaco difunda a través de la piel un coeficiente de reparto intermedio entre vehículo y membrana, un bajo grado de ionización y un peso molecular inferior a 500 Da. Asimismo, la integridad de la piel tiene un papel clave en la absorción cutánea, ya que los tejidos dañados facilitan enormemente el proceso de absorción.

Como resultado de la estructura anatómo-fisiológica de la piel, la administración de fármacos sobre la misma puede tener dos objetivos: terapia local o administración transdérmica con fines sistémicos. En concreto, esta administración del fármaco sobre la piel puede perseguir diferentes objetivos: a) permanecer sobre la piel para proteger el organismo o hacer frente a entidades vivas existentes en la superficie de la piel (por ejemplo, filtros solares, repelentes o productos

antifúngicos/antibacterianos); b) tratar diferentes trastornos de los anejos cutáneos (antitranspirantes o antiinfecciosos); c) tratar diversas afecciones del *estrato córneo* y de la epidermis viable (emolientes, exfoliantes, antiinflamatorios, antihistamínicos, etc.); d) modificar la función barrera de la piel para mejorar la absorción de otros fármacos; y, e) conseguir efectos sistémicos.

De entre todos estos objetivos, el más complejo, desde el punto de vista tecnológico, es el logro de una acción sistémica, a consecuencia de la mencionada acción barrera que la piel ejerce frente a la entrada de sustancias exógenas al cuerpo. Esta función barrera se debe principalmente a la presencia de la capa más superficial de la piel, el *estrato córneo*, debido a su carácter lipófilo y a la gran cohesión entre las células. Hay varios ejemplos bien conocidos de tratamientos que siguen este enfoque o estrategia terapéutica, específicamente terapias hormonales (estradiol), analgésicas (fentanilo) y deshabitación tabáquica (nicotina).

1.2. Sistemas de Administración transdérmica de fármacos

Los sistemas de administración transdérmica de fármacos (SAT) son un conjunto amplio de estrategias, recursos y herramientas que, mediante la modificación de la función barrera de la piel o el cambio de las propiedades fisicoquímicas de los fármacos, tienen como objetivo aumentar la absorción transdérmica de aquellos fármacos que no son buenos candidatos por sí mismos para difundir en cantidades adecuadas a través de la piel. El SAT ideal debe presentar las siguientes propiedades: a) ser atóxico, no irritante ni alergénico; b) proporcionar una acción rápida y con una duración del efecto predecible; c) ser farmacológicamente inerte; d) permitir una fácil retirada tras su uso; e) permitir la restauración rápida de las propiedades de la piel después de su eliminación; f) ser compatible con excipientes y fármacos; g) ser cómodo y cosméticamente aceptable; y, h) ser económico. Desafortunadamente, ningún SAT presenta todas estas propiedades juntas.

1.3. Liposomas, transfersomas y etosomas

La nanotecnología tiene como objetivo desarrollar una gran variedad de sistemas y partículas de tamaño nanométrico (de 1 a 1000 nm), donde puedan incorporarse diferentes fármacos. Uno de los campos de aplicación más importantes de estos sistemas es la nanomedicina y, más concretamente, en mejorar la biodisponibilidad y administración de fármacos. En la década los 60, los liposomas se diseñaron como nanovehículos con funciones programadas específicas, y se convirtieron en los precursores de varias nanopartículas utilizadas hoy en día. No mucho tiempo después, aparecieron variaciones en los componentes estructurales de estos liposomas, como es el caso de los transfersomas y etosomas, con el fin de mejorar sus propiedades, lograr una mayor eficacia y mejores resultados. Actualmente, estas variaciones estructurales siguen siendo diseñadas y estudiadas de forma habitual para satisfacer las necesidades y demandas de la industria farmacéutica y la práctica clínica.

Las vesículas lipídicas son partículas formadas por biomembranas no tóxicas y biodegradables obtenidas artificialmente, que han evolucionado gradualmente con el tiempo. Se han utilizado con éxito como transportadores de fármacos para la administración controlada y dirigida de fármacos. Su uso resulta muy atractivo, ya que su naturaleza lipófila permite incorporar fármacos poco solubles en medios acuosos y mejorar las propiedades de penetración de los fármacos a través de la piel. También se han documentado otras ventajas, como una mayor estabilidad de moléculas fotosensibles, menor degradación del fármaco y la posibilidad de conseguir un efecto depósito que libere paulatinamente su contenido.

1.4. La cianocobalamina como fármaco para el tratamiento de enfermedades de la piel con carácter inflamatorio

La cianocobalamina (B12) es una vitamina hidrosoluble que se almacena en el hígado y juega un papel clave en el metabolismo de las proteínas, en la formación de glóbulos rojos y en la homeostasis del sistema nervioso central. Por un lado, como vitamina es un nutriente

esencial que debe obtenerse a partir de la dieta, y su deficiencia tiene un impacto negativo en la salud. Por otro lado, su actividad como neutralizador del óxido nítrico hace que pueda aplicarse potencialmente con otros fines terapéuticos.

La deficiencia de B12 es la causa más común de ciertas patologías hematológicas, síntomas neuropsiquiátricos y otras enfermedades. Los bajos niveles de adenosil-B12 o metil-B12 en el organismo son consecuencia habitual de la deficiencia de B12. Esto produce alteraciones en los procesos de metilación y metabolismo del metilmalonato, un metabolito derivado del catabolismo de aminoácidos y ácidos grasos. En particular, los niveles bajos de adenosil-B12 producen una acumulación de ácido metilmalónico, que puede asociarse a la aparición del síndrome neurológico. Por su parte, la deficiencia de metil-B12 conduce a una acumulación de homocisteína, que puede inducir el estrés celular, la apoptosis y homocisteinilación de proteínas.

La deficiencia de B12 tiene principalmente tres etiologías o causas: trastornos de carácter autoinmune, malabsorción o baja ingesta dietética. La deficiencia autoinmune es una patología en la que la producción de anticuerpos anti-factor intrínseco bloquea su actividad, produciendo una incapacidad para absorber la vitamina. Las causas de malabsorción están asociadas con una producción ineficiente de factor intrínseco por parte de las células parietales en el estómago. Esta patología es muy frecuente en casos de bypass gástrico o enfermedades del íleon (cirugías, enfermedad de Crohn o infecciones por *Diphyllobothrium latum*). Por último, estilos de vida con una creciente implantación en la sociedad, como el veganismo, pueden conducir a una situación carencial al cabo de algunos años. Otras condiciones menos frecuentes como la deficiencia genética de transcobalamina-II y el uso de ciertos medicamentos (anticonceptivos orales, terapias de reemplazo hormonal, metformina, inhibidores de la bomba de protones y antagonistas histamínicos H2) también pueden ser causa de la deficiencia de B12. Su prevalencia en áreas desarrolladas,

como América del Norte y Europa, varía de 2.9-25.7%, dependiendo del punto de corte de los valores séricos (<148 y <256 pmol/L de B12, respectivamente). Además, varios estudios sugieren que aumenta con la edad y es más frecuente en mujeres que en hombres (3,3% frente 2,4% respectivamente, para niveles séricos <148 pmol/L). Además, el impacto en áreas en desarrollo, como África, América del Sur y Asia, es significativamente mayor y no se limita solo a grupos de mayor edad, superando el 40% de prevalencia en ciertas subpoblaciones (niños, adultos jóvenes y mujeres embarazadas).

El abordaje terapéutico de la deficiencia de B12 depende de diferentes factores como la etiología y la gravedad, y varía en función de su duración y vía de administración. Consiste, principalmente, en la reposición de los depósitos vitamínicos mediante inyecciones intramusculares o dosis orales de cianocobalamina. En caso de un funcionamiento anómalo de la vía del factor intrínseco se pueden administrar 1000 µg de cianocobalamina por vía intramuscular diariamente durante 1-2 semanas. Reducir la posología durante el mes siguiente a una vez por semana, y continuar con una inyección de mantenimiento mensual. Sin embargo, la vía intramuscular presenta ciertas desventajas, como la generación de molestias y dolor, necesidad de material y técnicas asépticas, costos asociados a su administración por personal capacitado, no ser aplicable en pacientes con baja masa muscular, y propiciar complicaciones médicas como formación de trombos, lesión de nervios -en inyecciones femorales y glúteas- o reacciones de hipersensibilidad. Como alternativa, es posible recibir B12 por vía oral, pero los principales problemas son su baja biodisponibilidad (1-4%) y su ineficacia en las etiologías relacionadas con el factor intrínseco.

En cuanto al uso de B12 como fármaco para patologías no relacionadas directamente con su déficit, se está estudiando su potencial aplicación en el tratamiento de enfermedades inflamatorias crónicas de la piel. El eccema o dermatitis atópica y la psoriasis son los más comunes, ya

que los mecanismos moleculares subyacentes de las mismas brindan una oportunidad para el uso de B12 como una posible terapia. La dermatitis atópica o de contacto se caracteriza por prurito, piel seca, y lesiones eczematosas. El inicio de la dermatitis atópica ocurre comúnmente durante la infancia y se asocia con una morbilidad significativa y calidad de vida reducida. Su prevalencia ha aumentado en los últimos 30 años, y su incidencia se ha duplicado o triplicado en los últimos años. Aproximadamente, el 20% de los niños y el 1-3% de los adultos se ven afectados por este trastorno. Aunque la patogénesis de la dermatitis no se comprende por completo, se ha asociado a varios factores: alteración de la función de barrera de la piel, desregulación inmunitaria, infecciones y procesos ambientales. Las alteraciones en la función de barrera de la piel pueden deberse a: niveles bajos de ceramidas y proteínas involucradas en la diferenciación de queratinocitos y la prevención de la pérdida transepidérmica de agua. Varios factores genéticos, como las mutaciones en los genes de la filagrina, pueden causar esta situación. La función defectuosa de la barrera permite la penetración de alérgenos y agentes irritantes que desencadenan la inflamación a través de respuestas Th2 (con aumento de citoquinas IL-4, IL-5, IL-13) en casos agudos, y respuestas Th1 (con aumento de IFN-gamma e IL-12) en lesiones crónicas. Además, el rascado de las lesiones, el cual es habitual en la mayoría de los pacientes, estimula la liberación de citocinas inflamatorias por los queratinocitos, como TNF-alfa, IL-1 e IL-6, que perpetúan la inflamación crónica. En última instancia, el mal estado de la piel contribuye a su colonización por bacterias, lo que empeora aún más el trastorno.

La psoriasis es una enfermedad inflamatoria crónica de la piel con un marcado componente inmunológico. Su signo más característico es la presencia de placas eritematosas habitualmente diseminadas por amplias zonas del cuerpo. La prevalencia a nivel mundial varía entre el 1-8%, dependiendo del área geográfica. Aunque puede comenzar a cualquier edad, su inicio se produce con frecuencia en la edad adulta, presentándose en uno de cada tres casos durante la infancia. Una característica

importante en los mecanismos moleculares causantes de la psoriasis es la activación del sistema inmunitario de forma alterada, lo que conduce a la hiperplasia de los queratinocitos, alteración de la función de las células T y angiogénesis. Además, el estrés oxidativo también tiene un papel destacable en la patogénesis de esta afección.

Los principales objetivos de los tratamientos de estas patologías son restaurar la barrera cutánea, limitar el picor, disminuir la inflamación y controlar las alteraciones a nivel inmunitario. Para conseguirlo es posible utilizar una gran variedad de fármacos, siendo los agentes inmunosupresores sistémicos, corticoides e inhibidores de la calcineurina tópicos (ICT) los fármacos de primera línea en el manejo farmacológico de la dermatitis y la psoriasis. Sin embargo, los tratamientos sistémicos no están exentos de posibles efectos secundarios adversos severos, como disfunción renal y hepática o mielo-supresión, que complican en gran medida el abordaje terapéutico de los casos graves. Los efectos secundarios locales asociados al uso crónico de esteroides tópicos e ICT son relativamente comunes, como atrofia de la piel, equimosis, erosiones, estrías, retraso en la cicatrización de heridas, púrpura, hematomas fáciles y acné. Además, la FDA ha relacionado el riesgo de sufrir cáncer de piel y linfomas con el uso de algunos ICT.

Sin embargo, el motivo principal para utilizar la B12 en este contexto radica en que las citocinas proinflamatorias implicadas en la dermatitis y la psoriasis estimulan la expresión de la enzima óxido nítrico sintasa inducible en los queratinocitos. En consecuencia, estas lesiones cutáneas presentan niveles elevados de óxido nítrico, los cuales pueden ser reducidos y, por tanto, controlados gracias a las propiedades neutralizantes de la B12.

La B12 oral y tópica ya se ha utilizado como alternativa para prevenir o mejorar la dermatitis y la psoriasis. Aunque los primeros ensayos datan de los años 60, no se han realizado muchos otros estudios hasta la actualidad. Januchowski et al. (2009) utilizando la escala SCORAD compararon el efecto de una crema de B12 con una base hidratante en el

tratamiento del eccema infantil en un ensayo aleatorizado doble ciego. Las comparaciones intraindividuales mostraron diferencias significativas en la reducción de los valores SCORAD entre la crema de B12 y el placebo. En particular, la B12 tópica mejoró significativamente la piel tratada más que el placebo a las 2 y 4 semanas. Más recientemente, la psoriasis leve-moderada en forma de placas fue tratada con pomadas tópicas de B12 durante 12 semanas en dos ensayos clínicos aleatorizados. Stücker et al. (2001) compararon el efecto de la B12 con el del calcipotriol (análogo de la vitamina D3), obteniendo reducciones similares en la puntuación PASI tras el periodo estudiado. Además, también se observó una marcada reducción de la eficacia del calcipotriol después de 4 semanas de tratamiento, mientras que la eficacia de la vitamina B12 se mantuvo prácticamente constante durante todo el estudio. Del mismo modo, se obtuvo un resultado positivo al comparar los efectos de la B12 y una crema emoliente en el estudio realizado por Del Duca et al. (2017). Las diferencias en la reducción de la puntuación PASI se reflejaron en la semana 2 y aumentaron durante las siguientes 10 semanas. Dos semanas después de finalizar el tratamiento, las lesiones psoriásicas evolucionaron positivamente, especialmente aquellas tratadas con B12. A pesar de estos prometedores resultados, el peso molecular (1355 Da) y la hidrofilia de la B12 limitan su difusión a través de la piel humana. Es por ello por lo que, el abordaje nanotecnológico o con microagujas puede suponer una mejora sustancial respecto a los resultados obtenidos hasta la fecha.

1.5. Estructura de las vesículas lipídicas y clasificación

Dependiendo del método de producción y composición, es posible obtener diferentes tipos de vesículas lipídicas. Según la carga superficial que confieren los fosfolípidos, las vesículas lipídicas se pueden clasificar en aniónicas, catiónicas o neutras. Además, el tamaño y número de bicapas lipídicas es la otra característica habitual para diferenciarlas. Las vesículas multilamelares (MLV) son aquellas que presentan más de una bicapa, que encierran el mismo número de compartimentos acuosos. Por

tanto, las vesículas unilaminares tienen una sola bicapa y un núcleo acuoso central. Estos dos ambientes tan diferentes hacen de las vesículas lipídicas un sistema de formulación muy versátil, ya que pueden albergar fármacos disueltos en el núcleo acuoso o insertados dentro de la estructura de la bicapa lipídica. Los MLV suelen presentar un tamaño relativamente grande, oscilando entre la escala nanométrica hasta 1 μm . Cuando el número de bicapas es inferior a cuatro, se denominan vesículas oligolamelares. Se ha demostrado que su eficacia de encapsulación del fármaco suele ser superior a la de las MLV. Un caso especial son las vesículas multivesiculares, que presentan una gran bicapa que confina múltiples vesículas en su interior. Las vesículas unilamelares se subclasifican a su vez en vesículas unilamelares pequeñas (SUV) y vesículas unilamelares grandes (LUV). Los SUV suelen presentar una forma esférica, distribución de tamaños homogénea, y un tamaño inferior a 100 nm, por lo que la eficacia de encapsulación de los fármacos hidrófilos es limitada. Por el contrario, las LUV son vesículas más grandes (100-1000 nm) con un núcleo acuoso con mayor volumen, lo que aumenta la capacidad de encapsular moléculas hidrosolubles.

1.6. Mecanismos de acción de los liposomas y vesículas ultraflexibles

Se ha demostrado previamente que los liposomas pueden interactuar eficazmente con las células por diferentes métodos: a) absorción por interacción específica con componentes de la superficie celular, fuerzas electrostáticas e hidrofóbicas; b) endocitosis por células fagocíticas, por ejemplo, macrófagos y neutrófilos; c) fusión mediante la inserción de las bicapas de las vesículas con las membranas celulares; y, d) intercambio de los componentes de las bicapas.

Sin embargo, los mecanismos de acción cuando las vesículas lipídicas se aplican sobre la piel todavía no están totalmente claros. En general, se acepta que los liposomas convencionales no logran penetrar las capas de la piel y permanecen en su superficie, actuando como una especie de formulación de depósito. Los liposomas pueden interactuar

directamente con la piel e intercambiar el fármaco mediante un fenómeno conocido como “proceso de transferencia del complejo de colisión”, el cual ha sido observado en otros sistemas biológicos, o bien podrían liberar al medio exterior el fármaco contenido desde donde puede difundir a través de la piel de forma natural. En este último caso, los liposomas no solo realizan una función de depósito, sino que pueden inducir cambios estructurales en el *estrato córneo* facilitando, de este modo, la absorción del principio activo. Todas estas teorías excluyen la penetración de la estructura del liposoma intacta, que ya ha sido ampliamente evaluada en diferentes estudios. Por ejemplo, Dreier et al. (2016) combinaron la microscopía STED y la espectroscopía RICS para estudiar el mecanismo de acción de los liposomas convencionales destinados a la vía transdérmica. Las imágenes obtenidas a partir de las muestras de tejido cutáneo incubadas con liposomas radiomarcados mostraron que no permanecen intactos una vez han penetrado las diferentes capas de la piel, sugiriendo que los liposomas no actúan directamente como transportadores que llevan su carga directamente a través de la piel. La limitada eficacia de los liposomas convencionales también se ha observado cuando son utilizados para superar otras barreras biológicas, como el epitelio intestinal. En el estudio de Dreier et al. (2016), se comparó la penetración de los liposomas convencionales con vesículas ultraflexibles y, como era de esperar, las vesículas ultraflexibles marcadas con fluorescencia liberaron su contenido a una mayor profundidad dérmica. Este hallazgo apoya la existencia de un mecanismo adicional involucrado para los transfersomas y demás vesículas ultraflexibles. Desde su concepción, se ha sugerido que este tipo de vesículas lipídicas pueden atravesar la estructura de la piel en un proceso que tiene un gradiente osmótico como fuerza motriz, que aparece debido a la diferencia en la concentración de agua entre la superficie de la piel (cerca del 15% en el *estrato córneo*) y las capas viables de la epidermis (alrededor del 75%). En concreto, estas condiciones son suficientemente fuertes como para empujar entre 0,1 y 0,5 mg de material lipídico por hora y cm², que es un

flujo sustancialmente más alto que el producido típicamente por los gradientes de concentración. Como parece que ocurre con los liposomas convencionales, el mecanismo exacto mediante el cual los transfersomas mejoran la absorción transdérmica es el resultado de la combinación entre la vectorización del fármaco, la disrupción del *estrato córneo* y las características de deformabilidad concretas de cada tipo de vesículas ultraflexibles. Teniendo en cuenta que la desestabilización del *estrato córneo* que producen los transfersomas es más intensa debido a la acción de los emulgentes incorporados en las vesículas. Una confirmación de estos mecanismos de acción es el estudio realizado por Cevc et al. (2002) En su estudio evaluaron la ruptura de los liposomas al ser forzados a pasar través de una barrera semipermeable, detectando una capacidad notable de los transfersomas para mantener su integridad tras el proceso de extrusión en comparación con vesículas convencionales. Además, mediante CLSM y cromatografía de exclusión molecular se confirmó, en un modelo *in vivo*, la presencia de vesículas ultraflexibles intactas en el torrente sanguíneo. Hallazgos similares han sido obtenidos en varios estudios realizados por otros investigadores con diferentes tipos de vesículas ultraflexibles, como Niu et al. (2019) y Manconi et al. (2011).

Los etosomas se consideran como otro tipo de vesícula ultraflexible, ya que presentan también capacidad de penetrar a través de las capas epidérmicas manteniendo su estructura y tamaño originales. Los mecanismos de acción subyacentes son similares a los transfersomas con algunas pequeñas diferencias. Además de fluidificar la bicapa lipídica, el etanol también es un promotor químico de la absorción, puesto que promueve la desestabilización del *estrato córneo* por su interacción con los grupos polares de los fosfolípidos de la piel. Sin embargo, se ha observado que la mejora en la absorción producida por una formulación de etosomal es mayor que la producida por soluciones etanólicas de fármacos. Además, la evaporación del etanol una vez aplicado sobre la superficie de la piel, puede aumentar el efecto del gradiente de concentración en el proceso de absorción transdérmica.

1.7. Métodos de producción de vesículas lipídicas

Existen múltiples métodos de preparación de vesículas lipídicas, y cada uno de ellos presenta ciertas ventajas, desventajas y confiere características específicas a las vesículas producidas. Su selección depende de diferentes parámetros como: a) las propiedades fisicoquímicas del fármaco encapsulado y los componentes de la vesícula lipídica; b) la concentración mínima eficaz del fármaco y su toxicidad; c) el tamaño de vesícula deseado, índice de polidispersión (PDI) y carga superficial; y, d) la reproducibilidad de los lotes y producción en escala.

1.7.1. Métodos de producción de liposomas y transfersomas

El mecanismo molecular específico de formación de liposomas depende en gran medida del método de producción utilizado, aunque el principio básico subyacente son las interacciones hidrofóbicas/hidrofílicas entre los lípidos y las moléculas de agua, independientemente de la metodología elegida. La aplicación y transferencia de energía en forma de calor, agitación o sonicación contribuye a la disposición de las moléculas de lípidos en bicapas.

El método de Bangham, también conocido como método de hidratación de la película lipídica o “thin-film”, es el primer procedimiento descrito para obtener artificialmente vesículas lipídicas. Presenta tres pasos claros: 1) preparación de una mezcla orgánica de fosfolípidos/colesterol/surfactante; 2) eliminación del disolvente orgánico usando un rotavapor con el objetivo de producir una película delgada sobre la pared del matraz; 3) rehidratación con una solución acuosa calentando por encima de la temperatura de transición de fase de los fosfolípidos utilizados. A pesar de la simplicidad del método, la baja eficiencia de encapsulación en muchos casos y la producción de poblaciones heterogéneas de MLV hace que sean necesarios procedimientos adicionales para obtener vesículas lipídicas útiles para fines transdérmicos. Además, a lo largo de los años se han ido desarrollando diferentes métodos para superar las limitaciones del método original.

1.7.2. Métodos de producción de etosomas

Touitou et al. (2000) publicó por primera vez un método con el que obtener vesículas lipídicas con etanol como excipiente, proporcionando ventajas adicionales a las vesículas. El método propuesto consiste en preparar una fase etanólica al 20-50% p/p, calentar a 30°C bajo agitación (700 rpm). La adición gota a gota de una fase acuosa a una velocidad constante de 12 ± 0.5 mL/h conduce a la formación de los etosomas espontáneamente. La incorporación de los principios activos se puede realizar en la mezcla orgánica o en la solución acuosa, dependiendo de sus propiedades fisicoquímicas. Una vez se ha incorporado el volumen adecuado de agua, la dispersión de etosomas se mantiene en agitación durante 5 min y se homogeneiza mediante diferentes métodos para conseguir vesículas de tamaño y PDI deseados. Este procedimiento de producción de etosomas se conoce como método clásico en frío, y una de sus principales ventajas es que se realiza casi a temperatura ambiente, lo que permite preparar vesículas lipídicas cargadas con fármacos termolábiles.

1.8. Propiedades y parámetros clave en el diseño de vesículas lipídicas con fines de administración transdérmica

Para lograr una permeabilidad transdérmica altamente eficiente de los fármacos, las vesículas lipídicas deben presentar algunas propiedades clave, a saber: tamaño, morfología, PDI, potencial zeta, eficiencia de encapsulación, grado de deformabilidad, liberación del fármaco, estabilidad y biocompatibilidad. Estas propiedades están conectadas entre sí y, por lo tanto, los cambios en una de ellas provocan variaciones en las otras. En consecuencia, parece casi imposible conseguir la vesícula perfecta o ideal y el verdadero reto se centra en el desarrollo de un prototipo con un equilibrio adecuado entre todos estos parámetros clave.

A modo de regla general, se ha establecido que, a menor tamaño, mayor es la absorción transdérmica proporcionada por las vesículas lipídicas. En este sentido, la deformabilidad de las partículas también juega

un papel relevante y, a mayor grado de deformabilidad, mayor es el efecto potenciador de la absorción. Respecto a los valores de PDI, resultados inferiores a 0,3 garantizan poblaciones suficientemente homogéneas.

1.9. Microagujas

Las microagujas (MNA) son dispositivos que contienen proyecciones microscópicas en forma de aguja que pueden perforar el *estrato córneo* creando conductos que facilitan el flujo de moléculas con gran tamaño molecular (> 500 Da), proteínas y nanopartículas a través de la piel. El campo de las microagujas ha experimentado un crecimiento constante desde el registro de la primera patente de Gastrel y Place en 1971. Sin embargo, hubo que esperar hasta el año 2000 para ver la aparición de MNA solubles y las principales aplicaciones actuales que tienen las MNA, que incluyen la vacunación, el diagnóstico y las aplicaciones cosméticas. Las MNA son un campo claramente emergente dentro de la investigación farmacéutica, dado el creciente número de artículos publicados desde la aparición del concepto de “microagujas”. En concreto, el número de artículos sobre MNA era moderado hasta antes del año 2000, pero después, se ha producido un aumento progresivo del número de trabajos publicado año tras año. Un estudio ARIMA, que extrapola tendencias futuras a corto-medio plazo en base a datos previos, identificó y predijo una tendencia creciente que se está cumpliendo en la actualidad. El número de patentes registradas en los últimos años también muestra un crecimiento continuo del uso de MNA como sistemas de administración de fármacos. El interés en los sistemas basados en MNA está altamente relacionado con algunas de sus ventajas más notables, como, por ejemplo, la liberación controlada de fármacos y su facilidad de uso, ya que pueden autoadministrarse y retirarse fácilmente. Además, pueden considerarse un sistema de liberación transdérmica indoloro, porque el tamaño de las proyecciones de las MNA es suficiente para traspasar las primeras capas de la piel evitando el contacto con las terminaciones nerviosas presentes en la dermis.

1.10. Seguridad y eficacia de MNA

Al igual que cualquier formulación farmacéutica, las MNA deben cumplir los requisitos mínimos e indispensables de seguridad y eficacia para ser aceptadas como una verdadera alternativa a las tecnologías clásicas de administración de fármacos. Tres acontecimientos adversos no deseados pueden tener lugar después de la inserción de las MNA: dolor, infecciones y reacciones cutáneas locales (inflamación, eritema, irritación, etc.).

1.10.1. Dolor

La aceptación del paciente y el cumplimiento de la pauta terapéutica de un tratamiento con MNA depende, en gran medida, del dolor que generan en comparación con inyecciones convencionales. Varios estudios han demostrado que el dolor producido por las MNA depende de la longitud y el número de agujas en cada dispositivo. Gill et al. (2007) observaron que la inserción de las MNA es menos dolorosa que una producida por una aguja hipodérmica de calibre 26 G, estableciendo una correlación entre el nivel de dolor con el número y longitud de las MNA. En particular, los autores estudiaron el dolor producido por agujas de 480, 700, 960 y 1450 μm de longitud y demostraron que los niveles de dolor que producían variaban entre el 5-37% en comparación con los producidos por agujas hipodérmicas. Además, el aumento en el número de proyecciones produjo un aumento relativamente pequeño del dolor, del 5 -25%. Bal et al. (2008) testaron el dolor generado por MNA de menos de 550 μm de longitud, encontrando niveles de dolor muy bajos en todos los casos, sin diferencias significativas entre ellas. Sin embargo, la rotura de las MNA durante la inserción puede producir dolor y reacciones cutáneas, lo que está especialmente asociado con el uso de determinados materiales, como el vidrio y la cerámica.

1.10.2. Infecciones

Los canales creados por MNA pueden convertirse potencialmente en una puerta para la entrada de patógenos al organismo puesto que, el

desarrollo de procesos infecciosos está directamente relacionado con la alteración de la función de barrera de la piel. A su vez, el tiempo que los microcanales permanecen abiertos depende en gran medida de algunas características de las MNA, como la longitud de las puntas, según Kalluri et al. (2011), que estudiaron *in vivo* la cinética del cierre de los canales. Los investigadores observaron que este proceso dura entre 15-72 h dependiendo, entre otros factores, de las condiciones y del efecto de oclusión, resultando similar al estimado para un canal producido por una aguja hipodérmica. La función de barrera de la piel también se evaluó mediante los niveles de pérdida de agua transepidérmica (TEWL), y se concluyó que la piel solo necesita 4 h para recuperar su función de barrera después del tratamiento con microagujas de 550 μm de longitud. Bal et al. (2008). demostraron que el uso de microagujas más largas produce un mayor aumento en los valores de TEWL, ya que se observó una diferencia significativa en la respuesta entre agujas con 400 y 200 μm de longitud. Además, el estudio de Donnelly et al. (2009) mostró que la inserción con MNA conllevó una colonización bacteriana significativamente menor a la producida por una inyección hipodérmica convencional. En concreto, ningún microorganismo accedió a la epidermis viable en la piel perforada con MNA, a diferencia de los resultados obtenidos con agujas hipodérmicas. Por tanto, se puede afirmar que la correcta aplicación de MNA en la piel no parece provocar infecciones locales ni sistémicas, en circunstancias normales y pacientes inmunocompetentes.

1.10.3. Biocompatibilidad, inmunogenicidad y reacciones cutáneas locales

La presencia de objetos extraños o la incompatibilidad biológica de cualquier componente de las MNA puede desencadenar una inflamación, irritación o eritema en la piel durante o después del tratamiento. Bal et al. (2008) comprobaron el posible impacto de la longitud de las MNA en la irritación, y examinaron el enrojecimiento de la piel y el flujo sanguíneo. Ambos métodos permiten medir el eritema, que es uno de los indicadores fundamentales de la inflamación. Por un lado, se observaron cambios en

el enrojecimiento tras la aplicación de MNA sólidas de tipo metálico, que llegó a alcanzar los valores máximos de irritación a los 15 min, retornando a los valores basales en aproximadamente 90 min. Por otro lado, un aumento en la longitud de las MNA (200, 300 y 400 μm) se traduce en un aumento en el enrojecimiento, aunque solo las diferencias entre la menor longitud (200 μm) y el resto fueron estadísticamente significativas. Además, el tratamiento con MNA de varias longitudes no produjo diferencias significativas en el flujo sanguíneo. Por su parte, Vicente-Pérez et al. (2017) no encontraron en su estudio ninguna evidencia significativa de un aumento en los biomarcadores séricos de inflamación e irritación (TNF- α e IL-1 β) después de un uso prolongado de MNA de tipo polimérico.

La baja biocompatibilidad o las respuestas alérgicas no son frecuentes en los enfoques basados en MNA, especialmente en el caso de las compuestas por polímeros, ya que los materiales de fabricación se transfieren desde otros campos de la tecnología farmacéutica donde se ha garantizado la biocompatibilidad previamente. Sin embargo, otros tipos de MNA, como las sólidas y huecas (“hollow”), pueden dar lugar a algunos de estos problemas. Por ejemplo, las MNA de acero inoxidable pueden corroerse con el tiempo, una característica que se ha mejorado notablemente con el uso de titanio para su fabricación.

1.11. Métodos *in vitro*, *ex vivo* e *in vivo* para evaluar la penetración y la permeabilidad transdérmica de fármacos

Aunque los métodos *in vivo* son los procedimientos ideales para evaluar los efectos de cualquier sistema de administración de fármacos, muchos estudios muestran que las concentraciones sistémicas y locales del fármaco pueden estimarse y predecirse utilizando parámetros de permeabilidad de la piel. Por ejemplo, el coeficiente de permeabilidad, el coeficiente de difusión, el periodo de latencia y el flujo transdérmico, todos ellos calculados por métodos *in vitro* y *ex vivo*.

1.11.1. Métodos in vitro: Células de difusión

Las Células de Difusión de Franz (FDC) de tipo estático y vertical son el sistema más habitual en los estudios de permeabilidad transdérmica. Están compuestas por dos compartimentos separados mediante una membrana o tejido. La formulación del fármaco se administra al compartimento dador, y el receptor se llena con un medio acuoso adecuado que permita disolver el fármaco tras su paso a través de la barrera en estudio, en este caso la piel, para garantizar las condiciones sumidero ("sink"). Para imitar las condiciones *in vivo* este compartimento receptor se agita utilizando un imán y se regula a la temperatura fisiológica de la piel (32-37°C), introduciéndolo en un baño de agua templada o utilizando un sistema calefactor adicional que rodea la célula. La cámara receptora incluye un puerto de muestreo que permite la toma de muestras a los puntos temporales preestablecidos. Posteriormente, las muestras se analizan mediante un método analítico adecuado según la naturaleza del fármaco y cantidades permeadas.

1.11.2. Métodos ex vivo: Tape-stripping y stripping diferencial

La profundidad de penetración del fármaco en la piel y la farmacocinética cutánea suelen estimarse mediante métodos *ex vivo*. El tape-stripping destaca por ser una técnica mínimamente invasiva que elimina el *estrato córneo*. Consiste en colocar una biopsia de piel en un portaobjetos de vidrio, la cual se cubre con una máscara de aluminio dejando al descubierto el área de aplicación de la formulación. Posteriormente, se administra una cantidad conocida de la formulación bajo estudio y se incuba el montaje a 32°C durante un período de tiempo comprendido entre 2 y 6 h. Después de la incubación, se aplican secuencialmente entre 20-25 tiras de cinta adhesiva sobre la piel, en condiciones estandarizadas de presión, con la intención de eliminar progresivamente las capas de corneocitos y el fármaco contenido en ellas. Finalmente, dicho fármaco se extrae de las tiras adhesivas sumergiéndolas en un medio adecuado donde el fármaco es altamente soluble, para luego

cuantificarlo mediante un método analítico apropiado. Esta técnica, además, al ser mínimamente invasiva se puede realizar *in vivo* muy fácilmente.

El stripping diferencial es una técnica que consiste en una combinación de la técnica del tape-stripping con una biopsia en superficie de la piel con cianocrilato. Se considera la técnica más sencilla para determinar cuantitativamente la captación folicular de fármacos. Después de llevar a cabo un procedimiento de stripping convencional, tal y como se describe anteriormente, se aplica una cantidad adecuada de adhesivo instantáneo de cianocrilato sobre la piel previamente desprovista de corneocitos. Tras la polimerización del adhesivo, la capa o biopsia de cianocrilato se despega para generar un molde folicular y se procesa de manera similar a las cintas adhesivas del tape-stripping convencional.

1.11.3. Métodos in vivo: Microdiálisis

La microdiálisis es el método de referencia para obtener un estudio completo de los procesos farmacocinéticos en la piel. Consiste básicamente en colocar una sonda de diálisis semipermeable en la estructura y profundidad de la piel que se desea estudiar. Esta membrana de intercambio se encuentra conectada a una bomba de perfusión, que introduce un líquido receptor fisiológico. A causa de los procesos osmóticos y de difusión, el líquido perfundido es capaz de recoger el fármaco que ha permeado a través de la piel, y permite caracterizar con gran precisión el proceso de absorción. Sin embargo, los métodos *in vivo* conllevan grandes requerimientos de carácter ético, dificultades técnicas y elevado coste económico.

2. Objetivos

El objetivo principal de esta tesis es el desarrollo y caracterización de diferentes sistemas de administración transdérmica para mejorar la penetración y absorción cutánea de B12, con la intención de ofrecer una alternativa factible a las terapias actuales para tratar la deficiencia de B12 y la dermatitis atópica o de contacto.

Para lograr este objetivo, el proyecto se dividió en los siguientes subobjetivos:

- **Objetivo 1:** Desarrollo de un método analítico por cromatografía líquida de alta eficacia que fuera exacto y preciso para la detección y cuantificación de B12.
- **Objetivo 2:** Desarrollo y caracterización de vesículas lipídicas de B12 (liposomas, transfersomas y etosomas), con énfasis en el estudio de su biocompatibilidad, estabilidad y otras propiedades predictoras de una óptima penetración y permeabilidad cutánea del fármaco (eficiencia de encapsulación, tamaño, flexibilidad y liberación del fármaco).
- **Objetivo 3:** Desarrollo y caracterización de MNA solubles de B12, evaluando especialmente sus capacidades para superar el *estrato córneo* y propiedades de liberación del fármaco.
- **Objetivo 4:** Evaluación *ex vivo* e *in vitro* de la penetración y permeabilidad de B12 a través de la piel proporcionada tanto por vesículas lipídicas como MNA solubles, estableciendo una comparativa entre estos resultados y los obtenidos a partir de una solución de B12 como referencia estándar.
- **Objetivo 5:** Comprobar la eficacia de uno de los sistemas diseñados en un modelo *in vivo* de hipersensibilidad de tipo retardado que simule una enfermedad de la piel con carácter inflamatorio, en este caso dermatitis de contacto o atópica.

3. Métodos

Los métodos empleados para la realización de esta tesis doctoral se resumen a continuación.

3.1. Cromatografía líquida de alta eficacia

La B12 se cuantificó en todos los experimentos mediante cromatografía líquida de alta eficacia (HPLC) o espectroscopia UV-Vis.

Para ello, se utilizó un HPLC PerkinElmer Series 200[®] equipado con un inyector automático y un detector UV-vis (PerkinElmer; Waltham, MA, EE. UU). La fase móvil consistió en una mezcla isocrática de metanol:agua (30:70). La fase estacionaria utilizada fue una columna de HPLC Kromasil[®] C18 de 5 µm de tamaño de partícula, tamaño de poro 100 Å, L x I.D. 150 mm x 4,6 mm (Dr. Maisch GmbH; Ammerbuch, Alemania). El volumen de inyección fue de 50 µL y para la detección se utilizó una longitud de onda de 360 nm. El flujo para introducir la fase móvil en el equipo se reguló a 0,7 mL/min y el análisis de las muestras se realizó a temperatura ambiente. El método fue validado en términos de linealidad, sensibilidad, precisión y exactitud.

3.2. Preparación de liposomas, transfersomas y etosomas

Se prepararon varias formulaciones de liposomas y transfersomas por el método de Bangham. Brevemente, se disolvió en metanol el Phospholipon 90G[®] (P90G), el colesterol (Chol) -relación molar P90G:Chol 17:1- o los tensioactivos (P90G:Tween 15% p/p), y la B12. El disolvente se evaporó utilizando un rotavapor bajo agitación, en condiciones de temperatura y presión de 50°C y 100 mbar respectivamente (BUCHI R-210, Büchi AG; Flawil, Suiza). La película de fosfolípidos resultante se hidrató mediante la adición de una solución salina amortiguadora de fosfatos (PBS) pH 7,4 o de una solución B12 y, a continuación, se agitó durante 1 h a 50°C para obtener una dispersión de MLV.

Los etosomas se prepararon por el método de Tuitou, disolviendo el P90G y la B12 en etanol. A continuación, se añadió una cantidad

adecuada de agua a un flujo de $12 \pm 0,5$ mL/h en un vaso de precipitados sellado bajo agitación (710 ± 5 rpm). El sistema se mantuvo en agitación durante 5 min tras la adición del agua.

Una vez obtenidos los MLV, se redujo su tamaño mediante sonicación y extrusión. En el caso de los liposomas y transfersomas, primero se sonicaron a 50°C durante 2 h (Elmasonic S60H, Elma; Singen, Alemania). Luego se enfriaron a 4°C y se extruyeron a través de una membrana de $200\ \mu\text{m}$, utilizando un LiposoFast-Basic Extruder (Avestin; Ottawa, Canadá). Los etosomas se trataron con ultrasonidos durante 1 h a temperatura ambiente y se extruyeron al igual que las otras vesículas lipídicas. Tras la reducción de tamaño, las muestras se purificaron por centrifugación ($12800\ \text{xg}$, 30 min) o se lavaron en 2 L de PBS a 4°C durante 24 h. Los lotes se almacenaron a 4°C protegidos de la luz en todo momento.

3.3. Preparación de MNA solubles

Se prepararon varios prototipos de MNA solubles utilizando alcohol polivinílico (PVA) y polivinilpirrolidona (PVP) como polímeros. Para ello, en primer lugar, se disolvieron los polímeros en agua para preparar mezclas madre, las cuales se utilizaron para preparar los geles con la concentración de polímero final deseada. Estos geles se mezclaron con vesículas lipídicas o B12 hasta lograr una homogeneidad completa de la mezcla. A continuación, se centrifugaron las mezclas ($3500\ \text{rpm}$, 15 min) para eliminar las burbujas de aire y se vertieron $0,25\ \text{g}$ en moldes de polidimetilsiloxano, que se colocaron en una cámara de presión positiva a 3-4 bar durante 45 min (Protima[®], TÜV Rheinland; Colonia, Alemania). Por último, para poder desmoldar las MNA, se secaron a temperatura ambiente durante 24-48 h.

3.4. Determinación del tamaño, PDI y potencial zeta de las vesículas

El tamaño de las partículas (diámetro medio) y PDI se midieron mediante un Nano zetasizer (Malvern Panalytical; Malvern, Reino Unido). Se utilizó el modo DLS para medir el tamaño de las vesículas y PDI,

mientras que el modo LDE se empleó para determinar el potencial zeta. Cada formulación se analizó por triplicado (n=3).

3.5. Determinación del contenido en fosfolípido de las vesículas

Se utilizó el método de Rouser et al. (1970) para determinar la cantidad de fosfatidilcolina incorporada a las diferentes vesículas. Brevemente, 100 µL de las suspensiones liposomales se calentaron a 270°C hasta la completa evaporación del agua. Luego se añadieron 450 µL de ácido perclórico (70 % v/v) y la mezcla se calentó a 250°C durante 30 min. Tras dejarla enfriar, se añadieron 3,5 mL de agua, 500 µL de molibdato de amonio (2,5 % p/v) y 500 µL de ácido ascórbico (10 % p/v). La mezcla resultante se agitó e incubó a 100°C durante 7 min. Una vez enfriados los tubos, se midió la absorbancia a 820 nm (espectrofotómetro HITACHI U-2900, Hitachi High-Tech Corp.; Tokio, Japón). Todas las formulaciones se analizaron por triplicado (n=3).

3.6. Determinación de la eficiencia de encapsulación de las vesículas

La eficiencia de encapsulación se determinó directamente calculando la cantidad de B12 encapsulada en las dispersiones de vesículas lipídicas.

Para ello, se incubaron 0,5 mL de dispersión de vesículas lipídicas durante 1 h con una mezcla de agua:metanol:dodecil sulfato sódico 1% (45:45:10) para disolver todos los componentes de la vesícula. La mezcla final se filtró y el contenido de B12 se analizó por HPLC. Todas las formulaciones se analizaron por triplicado (n=3).

3.7. Evaluación de la flexibilidad de las vesículas

La flexibilidad de las diferentes vesículas lipídicas se estimó indirectamente por extrusión en frío a través de una membrana de 100 nm. Para ello, se extruyeron 500 µl de cada formulación 9 veces a temperatura ambiente. También se registró el volumen final de dispersión recogido y se calculó la relación de disminución de tamaño de las nanopartículas mediante DLS. Todas las formulaciones se analizaron por triplicado (n=3).

3.8. Morfología de las vesículas

Las imágenes de las diferentes vesículas lipídicas se obtuvieron mediante microscopía electrónica de transmisión (TEM). Para ello, se diluyó una gota de las dispersiones vesiculares (1:1000). Esta dilución se depositó en una rejilla de cobre y se secó durante 4 min. Se eliminó el exceso de dispersión y se aplicó una gota de solución de ácido fosfotúngstico (2 %). A continuación, se visualizaron las vesículas utilizando un JEOL JEM 1010 -100kV- (Jeol Ltd.; Tokio, Japón).

3.9. Estudios de estabilidad de las vesículas

La estabilidad de las vesículas se comprobó semanalmente durante 60 días en términos de tamaño y PDI mediante DLS. Los fenómenos de coalescencia, floculación, cremado, sedimentación y clarificación se estudiaron durante las 24 h posteriores a la formulación de las suspensiones con un analizador de estabilidad Turbiscan™ LAB (Formulation SA; Toulouse, Francia). La estabilidad química de la B12 se evaluó semanalmente mediante la determinación del contenido del principio activo.

3.10. Liofilización de las vesículas

Las vesículas lipídicas se liofilizaron en ausencia y presencia de lactosa y sorbitol como agentes crioprotectores. Las soluciones de lactosa se prepararon con una relación molar 1:10 (fosfolípido:azúcar), mientras que las soluciones con sorbitol se prepararon al 2,5% v/v. Los etosomas no se liofilizaron, ya que el etanol puede ser eliminado con el procedimiento de liofilización. En todos los casos, se utilizaron 100 µL de muestra junto con 400 µL de crioprotector. Las muestras se congelaron a -80 °C durante 24 h (Ultra Low Temperature Freezer U570, New Brunswick Scientific; Enfield, CT, USA), y se liofilizaron durante 48 h utilizando un liofilizador LyoQuest HT-40 (Telstar; Barcelona, España) bajo condiciones controladas de temperatura y presión (-50 °C y 0,08 mbar). Las muestras liofilizadas se hidrataron con PBS y se comprobó la estabilidad de las vesículas en términos de tamaño y PDI mediante DLS.

3.11. Estudios de toxicidad de las vesículas en cultivo celular

Para los estudios de toxicidad, se utilizó la línea celular RAW 264.7 (ECACC; Salisbury, Reino Unido). Las células se mantuvieron en medio de Eagle modificado de Dulbecco (DMEM) suplementado con 10% de suero bovino fetal (FBS), penicilina (100 UI/mL) y estreptomycin (100 µg/mL), bajo una atmósfera humidificada con 5% de CO₂ y a una temperatura de 37°C.

Para los ensayos de proliferación y viabilidad celular se sembraron suspensiones de células a una densidad de $1 \cdot 10^6$ células/mL en placas de 96 pocillos (200 µl/pocillo) con medio DMEM suplementado al 10% con FBS, penicilina (100 UI/mL) y estreptomycin (100 µg/mL). Tras una incubación de 2 h, el medio se sustituyó por el mismo volumen de medio DMEM suplementado con 0,5% de FBS y se expuso durante 24 h a 10 µl de cada tipo de formulación de vesículas lipídicas a diferentes concentraciones. A continuación, se descartó el medio y se añadieron 100 µl de solución de MTT (0,5 mg/mL). Se eliminó el sobrenadante después de 1 h y los depósitos azules correspondientes al metabolito coloreado se disolvieron en 100 µL de DMSO. Se midió la absorbancia a 510 nm utilizando un lector de placas VICTOR3 Multilabel (PerkinElmer; Waltham, MA, USA).

3.12. Estudios de liberación del fármaco y ajuste cinético

Los estudios de liberación *in vitro* con las vesículas lipídicas se llevaron a cabo utilizando FDC con un área de difusión efectiva de 1,76 cm². Se añadieron 500 µl de cada formulación al compartimento dador, mientras el receptor se llenó con 12 mL de PBS pH 7,4 (n=6). Se utilizó una membrana de difusión Spectra/Por® para separar los compartimentos dador y receptor. Tanto el compartimento dador como el puerto de muestreo se cubrieron con Parafilm M® para garantizar la oclusión, evitar fugas y la evaporación del disolvente. Se recogieron muestras de 400 µL a las 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 24, 48 y 72 h, reponiendo el volumen tomado por PBS a temperatura ambiente.

La B12 liberada se cuantificó por HPLC y se calcularon las cantidades acumuladas de B12 frente al tiempo. Los perfiles de liberación se ajustaron a diferentes modelos cinéticos matemáticos: Higuchi, Korsmeyer-Peppas, Kim, Peppas-Sahlin, de orden cero y de primer orden.

Para los estudios de liberación *in vitro* de las MNA, estas se colocaron en una placa de 12 pocillos llena con 5 mL de PBS atemperado a 37°C. Las muestras de 200 µL se recogieron a los 5, 10, 15, 20, 30, 40, 50, 60, 90, 120, 180, 240 min, reponiendo el volumen tomado por PBS atemperado. Finalmente, se determinó la cantidad de B12 liberada mediante espectrofotometría UV-vis.

3.13. Morfología de las MNA

La morfología de las MNA se observó mediante microscopía electrónica de barrido (SEM) (EVO LS 15 SEM, Carl Zeiss; Jena, Alemania). Para ello, las MNA se recubrieron con una capa conductora de oro (Q150 RS sputter coater, Quorum Technologies, Lewes, Reino Unido).

3.14. Resistencia mecánica y propiedades de inserción de las MNA

La resistencia mecánica de las MNA se evaluó utilizando un analizador de texturas TA-TX plus (Stable Microsystem; Haslemere, Reino Unido). Para ello, las MNA se visualizaron antes de la prueba utilizando un microscopio óptico para determinar la longitud de sus proyecciones (Leica ICC50 HD, Leica Microsystems; Wetzlar, Alemania). Seguidamente, se aplicó el modo de compresión del analizador con una fuerza de 32 N/MNA durante 30 seg para comprimir las MNA contra una superficie de acero inoxidable. Finalmente, se observaron de nuevo las MNA para determinar la disminución del tamaño de las proyecciones.

3.15. Ensayo termogravimétrico

El análisis termogravimétrico (TGA) se llevó a cabo utilizando un TG 209 F3 Tarsus (Netzsch; Waldkraiburg, Alemania). Los barridos de temperatura se realizaron de 25 a 200 °C a una velocidad de barrido de 10 °C/min. Se utilizó el software Netzsch Proteus Thermal Analysis 8.0

(Netzsch; Waldkrainburg, Alemania) para crear las líneas de base y termogramas.

3.16. Calorimetría diferencial de barrido

El análisis calorimétrico (DSC) se llevó a cabo utilizando un DSC 214 Polyma (Netzsch; Waldkrainburg, Alemania). Los barridos de temperatura se realizaron de 25 a 225 °C a una velocidad de barrido de 10 °C/min (575). Se utilizó el software Netzsch Proteus Thermal Analysis 8.0 (Netzsch; Waldkrainburg, Alemania) para crear las líneas de base y termogramas.

3.17. Distribución de fármaco en las capas de piel

La penetración del fármaco contenido en los diferentes tipos de vesículas lipídicas en las distintas capas de la piel se evaluó mediante la técnica de tape-stripping. Todos los estudios *ex vivo* e *in vitro* se realizaron con muestras de piel porcina y fueron aprobados por el Comité Ético de la Universidad de Valencia, bajo el número de protocolo H1540295606992 (Anexo III). Para el tape-stripping se separó la piel del tejido conectivo y se colocó en un portaobjetos, con la cara externa de la piel hacia arriba. Se colocó una máscara de aluminio sobre ella, y se dejó la zona de aplicación de las formulaciones al descubierto. Se administraron 100 µl de las formulaciones correspondientes, y el sistema se incubó a 32°C durante 2, 4 y 6 h. Cada prueba se realizó por triplicado (n=3). Tras la incubación, se aplicaron secuencialmente 20 tiras de cinta adhesiva (strips) sobre la piel utilizando un rodillo siguiendo un procedimiento estandarizado y, luego, se retiraron cuidadosamente con una pinza. La cantidad de *estrato córneo* eliminado se determinó mediante densitometría infrarroja (SquameScan™ 850A, Hailand electronic GmbH; Wetzlar, Alemania) y, seguidamente, las tiras se agruparon siguiendo la secuencia 1, 2, 3-5, 6-10, 11-15, 16-20. La cantidad de B12 presente en cada muestra se extrajo de los strips utilizando una mezcla de metanol:agua (50:50 v/v) como disolvente de extracción, ya que ofrece un ratio de recuperación de B12 óptimo dentro del intervalo establecido (100 ± 20%). Posteriormente, la B12 fue cuantificada por HPLC sin interferencias con el método analítico.

3.18. Permeabilidad *in vitro* de fármaco a través de la piel

La permeabilidad cutánea de la B12 obtenida con las vesículas lipídicas y MNA solubles se evaluó utilizando un sistema de FDC con un área de difusión efectiva de 1,76 cm². La permeabilidad cutánea obtenida para los diferentes sistemas vesiculares se comparó con la permeabilidad cutánea de una solución de B12 al 0,5% (p/v). Para los experimentos con las vesículas lipídicas se utilizó piel porcina intacta o pre-tratada con MNA de tipo sólido sin dermatomizar. En el caso de las MNA solubles, la permeabilidad de la piel se evaluó utilizando piel porcina dermatomizada (600 µm). En el montaje del sistema de FDC, la piel se colocó horizontalmente entre las compartimento dador y receptor con el *estrato córneo* hacia arriba. Para el tratamiento de la piel con las MNA sólidas y solubles, se aplicó firmemente una presión similar en todos los casos durante 30 seg.

En el caso de las vesículas lipídicas, se añadieron 500 µL de cada formulación al compartimento dador. El compartimento receptor se llenó con 12 mL de PBS pH 7,4 y la temperatura se mantuvo a 32 ± 1°C durante todo el experimento (n = 6). Se tomaron muestras de 200 µL en tiempos prefijados, dependiendo de la formulación ensayada y de la piel utilizada. En cada muestreo, el volumen recogido se reemplazó por el mismo volumen de PBS atemperado. La B12 liberada se cuantificó mediante el método HPLC descrito anteriormente, y se calcularon las cantidades acumuladas de B12 en función del tiempo. Los parámetros de permeabilidad se calcularon por regresión lineal del estado estacionario: J_{max} (µg/cm²/h), K_p (cm/h) y tL (h) como simplificación del modelo de difusión de Scheuplein.

3.19. Visualización de los microcanales creados por MNA de tipo sólido

La piel porcina tratada con MNA de tipo sólido se tiñó con una solución de azul de metileno (1% p/v) durante 1 minuto. A continuación, se limpió el lugar de inserción con agua para eliminar el exceso de colorante y se tomaron imágenes mediante microscopía óptica.

3.20. Estudios in vivo

3.20.1. Animales y condiciones de estabulación

Para los experimentos del modelo de hipersensibilidad de tipo retardado (DTH) se utilizaron un total de 42 ratones BALB/c. Los animales se mantuvieron en las instalaciones de la Universidad de Valencia durante 10 días antes de empezar los ensayos para su acondicionamiento. Posteriormente, se asignaron aleatoriamente los grupos experimentales. Todos los procedimientos se ajustaron a los principios de cuidado de los animales de laboratorio y fueron aprobados por el Comité Ético de Experimentación y Bienestar Animal (Anexo III).

3.20.2. Inducción de un modelo de hipersensibilidad de tipo retardado y evaluación del edema auricular

Para inducir la inflamación en el modelo DTH se utilizó oxazolona (OXA) disuelta en acetona al 1 y 3% p/v. Se afeitó el abdomen de los animales (día -1) y un día después se les sensibilizó mediante una única aplicación percutánea de 150 µl de solución de OXA al 3% p/v (día 0). En el día 5, se desencadenó la reacción de hipersensibilidad mediante la aplicación de 10 µl de solución de OXA al 1% p/v en cada lado de la oreja. En este estudio, se aplicaron 20 µl de cada formulación (10 µl/lado) en la oreja derecha tras la administración de OXA, 24 y 48 h después. Se aplicó también propionato de clobetasol tópico disuelto en acetona (0,025 mg/oreja), como tratamiento de referencia. El grosor de la oreja se midió antes de desencadenar la reacción de hipersensibilidad y a las 24, 48 y 72 h, utilizando un micrómetro (Absolute Digimatic 2[®], Mitutoyo GmbH; Neuss, Alemania). Finalmente, los animales fueron sacrificados mediante dislocación cervical y se tomaron las orejas para los estudios histológicos.

3.20.3. Imágenes de bioluminiscencia

Para la obtención de imágenes de bioluminiscencia (BLI) se utilizó un equipo IVIS Lumina X5 (PerkinElmer; Waltham, MA, USA). Los ratones se trataron con 0,2 mL de luminol (200 mg/kg i.p.; disuelto en PBS), y se obtuvieron imágenes 30 min después de la inyección bajo un protocolo

anestésico adecuado (inhalación de isoflurano). Se determinaron las emisiones totales de fotones a diferentes tiempos (3, 6 y 24 h).

3.20.4. Estudio histológico

Las biopsias se fijaron en solución de paraformaldehído al 4% p/v y luego se embebieron en parafina. Posteriormente, se tiñeron las secciones de piel (de 5 μ m de grosor) para visualizar las estructuras cutáneas. Para la tinción con hematoxilina y eosina, las muestras se sumergieron en una solución de hematoxilina de Harris y se lavaron para eliminar el exceso de colorante. A continuación, se trataron secuencialmente con una solución de diferenciación y una solución etanólica de eosina (50% v/v). Por último, se deshidrataron con una secuencia de soluciones alcohólicas, se montaron con líquido DPX. Los cortes histológicos también se tiñeron con el reactivo tricrómico de Masson. Para ello, las muestras se fijaron en reactivo de Bouin durante 12 h y luego se enjuagaron con agua destilada. Las secciones histológicas se tiñeron secuencialmente con hematoxilina de Mayer, solución etanólica de ácido clorhídrico (0,5% p/v), ponceau ácido, solución acuosa de ácido fosfomolibdico (1% p/v), azul de anilina y alcohol etílico (95% p/v). Por último, las muestras se hialinizaron con dimetilbenceno y se sellaron con un bálsamo neutro.

3.21. Análisis estadístico

Todo el procesamiento de los datos se realizó con Microsoft Excel 2016® (Redmond, WA, EE. UU.) y SPSS versión 22.0® (IBM Corp., NY, EE. UU.). Los datos se expresaron como la media \pm desviación estándar (SD), a menos que se indique lo contrario. Como requisito previo para las pruebas estadísticas, se verificó la normalidad, homocedasticidad y esfericidad en caso de ser necesario. La distribución normal de cada conjunto de datos se evaluó mediante la prueba de Shapiro-Wilk. La homogeneidad de las varianzas se confirmó mediante la prueba de Levene. Las varianzas de las diferencias entre todas las combinaciones de grupos relacionados se comprobaron mediante la prueba de esfericidad de Mauchly. El análisis estadístico se llevó a cabo mediante la prueba t-

student para comparaciones simples, ANOVA de una vía para pruebas con dos variables y ANOVA de dos vías para pruebas con tres variables. Todas las pruebas de ANOVA fueron complementadas por la prueba post hoc adecuada en cada caso. En concreto, se utilizó la prueba no paramétrica de Games-Howell en caso de heterogeneidad de varianzas. En caso de cumplirse el requisito de homocedasticidad, se utilizaron las pruebas de Bonferroni o Tukey cuando el número de comparaciones era bajo o alto respectivamente. La prueba de Gabriel se empleó si el número de muestras era diferente entre los grupos a comparar. Las diferencias estadísticas se consideraron significativas si los valores p eran inferiores al 5% ($p < 0,05$).

4. Resultados y discusión

4.1. Validación del método analítico para la detección de B12

El análisis de B12 mediante HPLC en las condiciones descritas dio lugar a un pico cromatográfico único y bien definido con un tiempo de retención de 3,5 min. La relación entre las áreas cromatográficas y las concentraciones de B12 se evaluó en el rango de concentraciones comprendido entre 10-0,039 $\mu\text{g/mL}$. La linealidad del método quedó demostrada por los coeficientes de determinación que fueron superiores a 0,999 en todos los casos. Los límites de detección y cuantificación del método calculados, a partir de los valores obtenidos para tres curvas diferentes ensayadas en tres días distintos, fueron de 0,033 $\mu\text{g/mL}$ y 0,11 $\mu\text{g/mL}$ respectivamente. La precisión y exactitud del método se evaluó mediante el coeficiente de variación y el error relativo. En términos generales, la validación del método fue completamente satisfactoria, ya que todos los cálculos se mantuvieron por debajo del umbral del 10%, como recomiendan las directrices de la OCDE para la validación de un método bioanalítico. La validación del método de espectroscopia UV-vis, también ofreció una validación adecuada, ya que ambos comparten el mismo principio de detección.

4.2. Preparación de vesículas lipídicas. Evaluación del tamaño de partícula, PDI, potencial zeta y eficiencia de encapsulación

Las mediciones de tamaño estuvieron dentro del intervalo esperado para los diferentes tipos de vesículas lipídicas. Aproximadamente 290 nm los liposomas convencionales, 180 nm los transfersomas y 150 nm los etosomas. Los datos obtenidos fueron similares para los descritos por Wu et al. (2019), cuyos liposomas convencionales tuvieron un tamaño comprendido entre 236-374 nm, dependiendo del porcentaje de colesterol incluido en la formulación. Los tamaños de los transfersomas obtenidos fueron similares a preparados anteriormente por Carreras et al. (2020), mientras que los lotes de etosomas reprodujeron exactamente el tamaño descrito por Toutilou et al (2000).

Cabe destacar que el tamaño tiene un impacto relevante en la permeabilidad del fármaco a través de la piel. Concretamente, las nanopartículas lipídicas con un diámetro de 300 nm o inferior pueden mejorar considerablemente la permeabilidad transdérmica de fármaco, ya que cuanto menor es el tamaño, mayor es la absorción obtenida. Basándose en este criterio, todas las vesículas formuladas en este trabajo deberían ser capaces de promover el acceso de la B12 a la epidermis y dermis y, en consecuencia, permitir su absorción sistémica. En concreto, los transfersomas y los etosomas fueron los candidatos más prometedores debido a su tamaño y propiedades teóricas de flexibilidad. Además, las nanopartículas con un tamaño en torno a los 210 nm, como las vesículas ultraflexibles obtenidas, pueden también penetrar en la piel por la vía transfolicular.

Los valores de PDI, como medida de la variabilidad del tamaño de las poblaciones de partículas, fueron inferiores a 0,3 en todos los casos, que es el valor de corte sugerido para considerar homogéneas las poblaciones en términos de tamaño con fines de administración transdérmica de fármacos. Los valores de potencial zeta de todas las formulaciones fueron negativos debido, principalmente, a la carga negativa

de los fosfolípidos. Los liposomas mostraron la carga más negativa, probablemente debido al mayor tamaño y mayor cantidad de fosfolípidos. Otra posible explicación a este resultado es que la carga superficial disminuye al aumentar el nivel de colesterol en una membrana de fosfolípido, como se ha demostrado previamente por otros investigadores. En cuanto a los transfersomas y etosomas, éstos presentan menor tamaño, probablemente debido a la presencia del tensioactivo, lo que implica una menor concentración en fosfolípidos, y reduce a su vez la carga negativa del sistema. Estos resultados son consistentes con los intervalos descritos por Ahad et al. (2017) y Touitou et al. (2000), quienes obtuvieron resultados similares para el mismo tipo de transfersomas y etosomas. Sin embargo, ninguno de los prototipos presentó un valor inferior a -30 mV, lo que predice una baja estabilidad a largo plazo de las vesículas lipídicas.

Una de las etapas clave en el proceso de producción de las vesículas lipídicas es la purificación de estas, en gran medida, porque para determinadas aplicaciones resulta fundamental la eliminación de la fracción de fármaco no encapsulada. La tasa de recuperación de fosfolípidos tras el proceso de producción demostró que la centrifugación es un método que solamente es adecuado para los liposomas convencionales. Por lo tanto, este método fue descartado para las vesículas ultraflexibles. Como alternativa, el método de diálisis se empleó con éxito para la purificación de los transfersomas. Sin embargo, este método tampoco parece ser adecuado para los etosomas debido a que el etanol también puede difundir fuera de las vesículas por su alta solubilidad en agua. Ante esta situación y debido a que las vesículas lipídicas pueden incrementar la permeabilidad de tanto la fracción encapsulada como de la no encapsulada, los etosomas empleados en los demás estudios no fueron purificados previamente.

En cuanto a la eficacia de encapsulación, hay que tener en cuenta que los compuestos hidrofílicos suelen mostrar menores tasas de encapsulación que los lipofílicos. Esto se debe a que el proceso de carga del fármaco es más eficiente si el compuesto queda retenido en las bicapas

de fosfolípidos, lo que depende principalmente de su afinidad primaria. Teniendo en cuenta esta premisa, aunque los resultados de eficacia de encapsulación no superaron el 50%, se encuentran en cualquier caso dentro en el intervalo esperado.

4.3. Morfología de las vesículas

En las imágenes obtenidas mediante TEM, se observaron vesículas multilamelares, ya que el método de Bangham tiende a producir MLV relativamente heterogéneas. Éstas presentaron forma esférica-ovoide, aunque con ciertas irregularidades debido al proceso de secado de la muestra. El tamaño de las partículas se ajustó satisfactoriamente a los resultados obtenidos mediante DLS. Sin embargo, las ligeras variaciones de tamaño pueden deberse a la preparación de las muestras que requieren procesos de deshidratación y secado.

4.4. Evaluación de la flexibilidad de las vesículas

La tasa de reducción del tamaño de las vesículas y la pérdida de volumen tras la extrusión en frío se utilizó como medida indirecta de la capacidad de deformación de las vesículas. Como era de esperar, se obtuvieron diferencias significativas entre los liposomas convencionales y las vesículas ultraflexibles. Mientras que los liposomas quedaron retenidos en los filtros de 100 nm y se vieron obligados a dividirse en partículas más pequeñas para pasar los poros, los transfersomas y los etosomas (cuyo tamaño inicial era superior a 100 nm) mantuvieron su tamaño durante el paso a través de la membrana porosa gracias a su flexibilidad.

Asimismo, el volumen final recogido tras la extrusión en frío está inversamente relacionado con la flexibilidad de la vesícula. Mientras que no se observaron diferencias en los lotes de transfersomas o etosomas, todos los prototipos liposomales presentaron una reducción significativa respecto a sus volúmenes iniciales. De este modo, ambas técnicas confirmaron la flexibilidad de los transfersomas y los etosomas en comparación con los liposomas convencionales.

4.5. Estudios de estabilidad de las vesículas

Las cinéticas de desestabilización global indicaron los índices de estabilidad sobre las vesículas de B12 (liposoma convencional < etosoma < transfersoma). Los transfersomas resultaron ser la formulación más estable, ya que no se registraron fenómenos característicos de inestabilidad, mientras que los etosomas, experimentaron un fenómeno de claro de floculación reversible, que también fue documentado previamente por Cristiano et al. (2019). Por el contrario, las vesículas liposomales experimentaron un proceso de sedimentación muy marcado.

La estabilidad física y química a largo plazo se monitorizó midiendo semanalmente el tamaño de la vesícula y PDI durante 2 meses, y el porcentaje de encapsulación durante 3 meses. No se encontraron diferencias significativas en el tamaño en función del tiempo de almacenamiento a 4°C, excepto para los liposomas convencionales transcurridas 4 semanas. Respecto al PDI, no se observó ningún cambio significativo durante el periodo de tiempo estudiado, lo que apunta a una evolución homogénea del tamaño de las poblaciones de vesículas.

Respecto al contenido de fármaco en relación con la cantidad inicialmente formulada, se detectaron cambios significativos en él en todos los prototipos entre las semanas 7 y 8. Esta pérdida o fuga de fármaco es relativamente habitual, especialmente en aquellas vesículas que contienen fármacos hidrofílicos. Teniendo en cuenta estos resultados, las vesículas lipídicas de B12 parecen mostrar una estabilidad a corto y medio plazo (al menos 1 mes para todos los parámetros comprobados), lo que las hace una herramienta prometedora para su aplicación clínica. Sin embargo, con el objetivo de aumentar su estabilidad para que pudieran ser almacenadas durante largos periodos de tiempo, se investigó la liofilización como método de preservación, ya que se ha demostrado que es un método excelente para garantizar la estabilidad de múltiples formulaciones farmacéuticas.

4.6. Liofilización, estudio calorimétrico y termogravimétrico de las vesículas

La estabilidad a largo plazo es uno de los mayores retos para la producción de liposomas y vesículas lipídicas modificadas, ya que las partículas basadas en lípidos pueden oxidarse fácilmente. Como se pudo observar, cuando se dispersan en una solución acuosa, pueden permanecer estables entre 2 y 3 meses, aunque los cambios de tamaño de partícula pueden darse a partir del primer mes de almacenamiento.

Tras la liofilización de las vesículas lipídicas, la inspección visual denotó que el uso de sorbitol no evitó el colapso de la muestra, dando lugar a un producto final subóptimo en términos de calidad. De este modo, el sorbitol se consideró como un crioprotector inadecuado para el tipo de muestra en estudio. Por el contrario, la lactosa logró preservar un producto uniforme sin evidencia de daños, y fue capaz de mantener estables los valores de tamaño y PDI previos a la liofilización. La calidad de los polvos liofilizados obtenidos se evaluó mediante la determinación del contenido de agua residual que fue en todos los casos de alrededor del 1%, un resultado adecuado teniendo en cuenta que el contenido máximo recomendado es del 3%.

4.7. Estudio de liberación de B12 a partir de las vesículas

Los estudios de liberación de fármacos *in vitro* se utilizan regularmente en el proceso de optimización de las formas farmacéuticas. Todas las formulaciones de vesículas lipídicas mostraron una liberación controlada del fármaco. Al contrario que la solución acuosa de B12, que se utilizó como control, ya que representa el perfil de difusión del fármaco sin las limitaciones producidas por la formulación en cuestión. Concretamente, después de 3 h de liberación, la cantidad de B12 detectada en el medio receptor fue significativamente mayor para la solución que para los liposomas, los transfersomas y los etosomas, tal como se esperaba. Además, también se observaron diferencias entre la liberación a partir de liposomas convencionales y vesículas ultraflexibles. La diferencia resultó

ser mayor en el caso de los liposomas, probablemente debido a su mayor rigidez, puesto que aquellas bicapas lipídicas que presentan poca flexibilidad se oponen en mayor medida al transporte o difusión del fármaco.

Los datos experimentales de liberación se ajustaron a diferentes modelos cinéticos para comprender mejor los perfiles de liberación: Higuchi, Korsmeyer-Peppas, Kim, Peppas-Sahlin, de orden cero y de primer orden. Este punto es muy recomendable, ya que la modelización matemática puede ayudar a comprender el posterior rendimiento *in vivo* de las formulaciones. En general, el modelo de Korsmeyer-Peppas presentó los valores AIC más bajos para casi todas las formulaciones, lo que es indicativo de un ajuste preciso.

Al contrario de lo que se esperaba para las vesículas ultraflexibles, el modelo de Korsmeyer-Peppas señaló que presentan un mecanismo de liberación mixto. Sin embargo, a tenor de los resultados, parece que la relajación o erosión tiene una mayor influencia durante las primeras horas de liberación y su peso se diluye con el transcurrir del tiempo, en favor de la difusión pasiva como mecanismo de liberación de la B12.

4.8. Biocompatibilidad celular de las vesículas

Las vesículas lipídicas permiten mejorar la administración transdérmica de fármacos sin considerables efectos adversos producidos por ellas mismas. Esto se debe a su excelente biocompatibilidad y a su facilidad para mezclarse con los lípidos de la piel, al contrario que otras nanopartículas. En algunos casos, incluso presentan una mejor biocompatibilidad que las disoluciones farmacológicas equivalentes.

Los datos obtenidos en los ensayos de proliferación celular mostraron una relación directa entre la viabilidad celular y la combinación dosis de B12-portador lipídico. Las formulaciones blancas (solo el vehículo sin fármaco) no solo no resultaron tóxicas, sino que se observó un efecto proliferativo, especialmente marcado en los liposomas y transfersomas. Teniendo en cuenta, por un lado, que las vesículas con una carga de

fármaco elevada pueden provocar efectos citotóxicos en las células, y, por otra parte, que las formulaciones blancas fueron completamente biocompatibles, parece claro que una dosis excesiva de B12 fue la principal responsable de la muerte celular observada en los casos en los que las vesículas lipídicas se suministraron a las células en cultivo sin ser debidamente diluidas. Sin embargo, cabe mencionar que los etosomas no mostraron ningún signo de toxicidad con la dosis inicial de B12 (1,3 mg/mL) tras su producción. Los transfersomas demostraron ser portadores citotóxicos intermedios, ya que la viabilidad celular observada fue más alta que la producida por liposomas convencionales administrados a la misma concentración de fármaco. Por último, hay que tener en cuenta que las concentraciones de B12 que pueden acceder a la piel son presumiblemente inferiores a las ensayadas en este experimento y, por tanto, no serían de esperar problemas de biocompatibilidad con las formulaciones de vesículas lipídicas de B12 desarrolladas en caso de ser administradas en cualquier modelo *in vivo*.

4.9. Preparación de MNA solubles

Para la preparación de MNA se utilizaron dispersiones acuosas de diferentes polímeros biocompatibles, solos o combinados, para preparar los prototipos finales de MNA solubles. En concreto, se emplearon tres polímeros diferentes: PVP y PVA (de bajo y alto peso molecular). Dos de las formulaciones diseñadas no sirvieron para producir MNA. Una de ellas contenía una mezcla de polímeros excesivamente viscosa que no permitió el vertido del gel en los moldes de polidimetilsiloxano. La segunda de estas mezclas, que contenía las vesículas lipídicas liofilizadas y PVA de bajo peso molecular (15% p/p), no pudo retener las vesículas lipídicas en la red polimérica después de la centrifugación previa al vertido del gel en los moldes. Además, cabe destacar que las vesículas lipídicas migraron a la fracción superior de la mezcla, como consecuencia de la baja densidad del polvo liofilizado. El resto de las formulaciones produjeron mezclas

poliméricas homogéneas, y las MNA resultantes presentaron proyecciones puntiagudas y afiladas al ser observadas al microscopio.

Las MNA mostraron un comportamiento flexible discreto tras ser desmoldadas. Una semana después, las MNA eran completamente resistentes a la deformación y alcanzaron su máxima resistencia y propiedades de inserción. Este hecho fue determinado mediante el análisis TGA que mostró que las MNA perdieron un porcentaje menor de peso (atribuible al agua residual) siete días después de la producción, en comparación con las MNA recién desmoldadas.

Las MNA se caracterizaron mediante DSC a partir de sus materiales constitutivos para estudiar las posibles interacciones polímero-polímero o polímero-fármaco y caracterizarlas para posteriores procesos de escalabilidad. Dependiendo del componente polimérico principal, los termogramas mostraron un perfil característico común.

4.10. Morfología de las MNA

Las imágenes obtenidas mediante SEM se emplearon para observar la morfología de las MNA y confirmar la longitud de sus proyecciones determinadas previamente mediante microscopía óptica. A nivel topológico, se observaron principalmente dos diferencias entre ellas. En primer lugar, la formulación de MNA que contenía B12 presenta una topografía lisa, mientras que las vesículas lipídicas liofilizadas interactúan con la superficie de las MNA dando lugar a un relieve irregular. En segundo lugar, la longitud de las proyecciones de los prototipos de MNA formulados con vesículas lipídicas fue significativamente menor que la de los otros prototipos de MNA. Este hecho se debe probablemente a que el alto contenido de la vesícula lipídica (10% p/p) produce un comportamiento diferente del polímero, con una mayor tendencia a la contracción tras la pérdida del agua contenida en las MNA, en comparación con la producida por el fármaco libre (1% p/p).

4.11. Resistencia mecánica y propiedades de inserción de las MNA

La evaluación de la resistencia mecánica se llevó a cabo para determinar la capacidad de las MNA para resistir la fuerza de compresión que es ejercida cuando se insertan en la piel. La resistencia mecánica de las MNA se determinó en base al porcentaje de reducción de la longitud de las proyecciones tras la aplicación de una fuerza de 32 N/MNA. La compresión de las MNA produjo una reducción significativa de la longitud de dichas proyecciones en todos los casos. Sin embargo, el porcentaje específico de compresión dependió de la combinación y concentración del polímero. Las MNA preparadas utilizando sólo PVP como polímero exhibieron las máximas reducciones de longitud y deformación de las proyecciones, lo que representa unas propiedades mecánicas insuficientes. Del mismo modo, el prototipo elaborado únicamente con PVA de bajo peso molecular también mostró una considerable reducción de la longitud de las MNA. Por el contrario, los prototipos formulados con una combinación de PVA y PVP exhibieron comportamientos de mayor resistencia a la compresión, especialmente aquellos que se formularon con PVA de alto peso molecular. Además, la incorporación de partículas lipídicas liofilizadas redujo la resistencia mecánica del prototipo en cuestión. Estos hallazgos concuerdan adecuadamente con los resultados previamente publicados, donde la combinación de PVP y PVA aumentó las propiedades mecánicas de las formulaciones debido a las interacciones de los puentes de hidrógeno establecidos entre los grupos -OH del PVA y los grupos C=O del PVP.

La potencial inserción de los prototipos se evaluó mediante un modelo artificial con Parafilm[®] M. Los resultados de inserción corroboraron las propiedades mecánicas de las MNA, ya que las mejores tasas de inserción fueron aquellas proporcionadas por los MNA formulados con la mayor concentración de la mezcla polimérica PVP-PVA de alto peso molecular.

4.12. Estudio de liberación de B12 a partir de las MNA solubles

El uso de diferentes polímeros para producir MNA que dio lugar a diferentes propiedades mecánicas y químicas, también influyó en el proceso de liberación del fármaco y en el mecanismo por el cual se produce. Aunque la liberación de principios activos a partir de MNA solubles se rige principalmente por la disolución de la matriz, otros mecanismos adicionales también son posibles. En general, los resultados de liberación volvieron a coincidir con las tendencias obtenidas en las pruebas de resistencia mecánica e inserción. La formulación basada únicamente en PVP mostró una liberación más rápida del fármaco que las combinaciones basadas en PVA-PVP. Por su parte, el prototipo basado en PVA de bajo peso molecular también mostró una liberación más lenta en comparación con la combinación de dos polímeros (PVA-PVP). Por el contrario, la adición de las vesículas lipídicas liofilizadas en el MNA dio lugar a estructuras poliméricas menos cohesionadas que liberaron su carga con mayor facilidad. Además, como las vesículas lipídicas presentan una limitación en cuanto a la carga de fármaco que pueden albergar en comparación las MNA que contienen el fármaco libre, su dosis de B12 fue considerablemente menor, aunque también se consiguió una liberación total del fármaco. Los prototipos elaborados con PVA de alto peso molecular fueron los únicos que conservaron la matriz polimérica una vez finalizado el proceso de liberación, lo que denota un mecanismo de liberación por relajación-hinchamiento del polímero alternativo y coexistente con la disolución de la matriz.

4.13. Penetración en piel *ex vivo* de B12 a partir de las vesículas

El espesor total del *estrato córneo* determinado mediante densitometría infrarroja fue de alrededor de 20 μm , coincidiendo con los valores estándar de entre 17-28 μm previamente obtenidos por Jacobi et al. (2007). Los estudios de penetración cutánea se realizaron con las formulaciones más prometedoras de liposomas, transfersomas y etosomas (L1, L2, T1d, T2d, E1 y E3). Además, se utilizó como referencia una

solución acuosa de B12 al 0,5 % p/v, ya que representa la difusión libre de fármaco sin los posibles efectos potenciadores de la absorción proporcionados por el vehículo.

Como tiempos de incubación se seleccionaron 2, 4 y 6 h, que abarcan aproximadamente el mayor tiempo que una formulación tópica puede mantenerse sobre la piel. Además, generalmente, las cantidades de B12 detectadas en las capas más profundas de la piel aumentan en función del tiempo de incubación, lo que facilita la interpretación de los resultados. En cualquier caso, la solución de B12 presentó la mayor cantidad de B12 extraída en el primer strip. No obstante, tras el tiempo máximo de incubación, la solución de B12 no fue capaz de penetrar más allá de 6 μm de profundidad, lo que confirmó la dificultad que presenta la B12 para difundir a través de la piel intacta. Sin embargo, las vesículas lipídicas (prototipos L1, T1d, T2d y E3) permitieron que la B12 alcanzara la dermis (más de 25 μm de profundidad).

4.14. Permeabilidad transdérmica *in vitro* de B12 a partir de las vesículas y MNA solubles

Al igual que los resultados de penetración a través de la piel, la permeabilidad de la B12 administrada en una solución acuosa fue prácticamente despreciable, ya que las concentraciones del fármaco que se obtuvieron en el medio receptor de la FDC, tras 32 h de estudio, se encontraron por debajo del límite de cuantificación mediante el análisis por HPLC. Por un lado, el uso de las vesículas lipídicas desarrolladas aumentó notablemente la permeabilidad de la B12 a través de la piel, siendo las vesículas ultraflexibles las que proporcionaron los mayores flujos transdérmicos de fármaco. Por otro lado, estos flujos fueron mayores a partir de aquellas formulaciones que presentaron menores porcentajes de eficacia de encapsulación, pero que, a su vez, contienen mayores dosis de fármaco. Por tanto, se puede concluir que la capacidad de mejorar la difusión de la B12 por parte de las vesículas lipídicas aumenta dependiendo de su flexibilidad y de la dosis incorporada.

La constante de permeabilidad (K_p) se calculó correlacionando el flujo con la dosis aplicada como medida de la eficiencia de cada vesícula y, de nuevo, los transfersomas y los etosomas fueron las formulaciones más eficaces. La comparación de J_{max} y K_p pone de manifiesto el rol que juega la dosis de fármaco contenida en las vesículas, ya que condiciona su actividad y eficacia final, como puede observarse en la comparación de los flujos entre los diferentes liposomas y transfersomas formulados con diferentes dosis. Por último, las vesículas ultraflexibles ofrecieron una disminución significativa del periodo de latencia, lo que produjo un inicio más temprano de la absorción y contribuyó a un aumento de la permeabilidad.

El pre-tratamiento de la piel con MNA de tipo sólido potenció en gran medida los resultados de permeabilidad obtenidos, ya que las MNA fueron capaces de abrir canales en la epidermis de mayor profundidad que el espesor del propio *estrato córneo*. A pesar de ello, el tiempo que dichos microporos permanecen abiertos en condiciones *in vivo* es objeto de controversia y discusión, por lo que se desarrollaron MNA solubles de B12 que no presentan esta limitación. Los resultados de permeabilidad de este tipo de MNA evidenciaron que, al igual que las MNA de tipo sólido, aumentan notablemente la absorción del fármaco. En cuanto a los perfiles de permeabilidad de estas MNA poliméricas, cabe destacar la existencia de dos fases bien diferenciadas. Una primera fase, correspondiente al efecto de inserción de las MNA que permite superar el *estrato córneo*; y una segunda, que tiene lugar tras la transición sólido-gel, tras la cual la B12 tiene mayor facilidad para difundir a través de la piel debido al estado líquido de la formulación.

4.15. Modelo *in vivo* DTH. Evaluación del edema auricular, estudios de bioluminiscencia e histopatológico

El aumento del grosor del pabellón auricular se considera una medida indirecta del edema de la piel de la oreja y de la permeabilidad vascular, ya que se encuentra típicamente aumentada en los procesos de dermatitis atópica y de contacto. Para estos experimentos, se seleccionaron los transfersomas y etosomas, ya que fueron los tipos de vesículas lipídicas que mostraron los mejores resultados en cuanto a la penetración y permeabilidad de la B12 a través de la piel. Es decir, se descartaron los liposomas convencionales y la solución acuosa de B12 como medida de reducción de animales en cumplimiento del principio de las 3 R.

El grosor del pabellón auricular aumentó en los grupos sensibilizados con OXA en comparación con los no sensibilizados (grupo control sano). Este aumento del grosor de la piel asociado al edema no se observó cuando los animales fueron tratados con clobetasol (1,25 mg/ml), lo que demuestra la idoneidad del modelo, ya que el proceso patológico puede ser plenamente revertido mediante un tratamiento con el fármaco adecuado. En concreto, se produjo una ligera disminución del grosor de las orejas, probablemente como consecuencia del adelgazamiento y la atrofia de la piel habitualmente inducida por el tratamiento con un esteroide.

El grupo no tratado (grupo OXA) mostró un aumento del grosor de la oreja de 308 μm después de 24 h, que remitió espontáneamente al resolverse el proceso inflamatorio, ya que los animales no fueron expuestos de nuevo al agente desencadenante. Los transfersomas cargados con B12 redujeron 182 μm el aumento del grosor de la oreja en comparación con el grupo no tratado a las 24 h. Las vesículas lipídicas sin fármaco también mostraron una reducción no significativa del edema o grosor cutáneo en comparación con el grupo no tratado, que puede ser atribuida a las propiedades emolientes de los componentes lipídicos y al efecto refrescante producido por el vehículo acuoso. Estos resultados

confirmaron la eficacia de la B12 como neutralizador del óxido nítrico. Sorprendentemente, los etosomas no produjeron un efecto significativo satisfactorio, a pesar de que en los estudios *in vitro* de penetración y permeabilidad fueron una de las formulaciones con mejores resultados. Una posible explicación es que la irritación producida por el etanol contrarrestó los efectos neutralizadores de la B12.

El modelo DTH utilizado genera una respuesta inflamatoria a través de neutrófilos, macrófagos y células T. Por lo tanto, se llevó a cabo un ensayo BLI con luminol para confirmar los hallazgos anteriores y estudiar si los neutrófilos están implicados en el proceso patológico desencadenado por la administración de OXA. En este ensayo se descartaron los grupos tratados con etosomas debido a los escasos resultados obtenidos en la reducción del grosor de las orejas. También se descartó el grupo de control sano, puesto que se utilizó la oreja izquierda como control intraindividual en cada animal. La sensibilización a OXA generó una emisión de fotones significativo entre las orejas derecha e izquierda, con una señal máxima después de 24 h, lo que confirmó la existencia de un cierto grado de infiltración leucocitaria. Como era de esperar, la BLI inducida por el luminol se normalizó completamente con el tratamiento con clobetasol, ya que los neutrófilos y los macrófagos son susceptibles típicamente de los efectos de supresión inmunitaria en tratamientos con corticoesteroides. Sin embargo, al contrario que en los estudios de edema en la oreja, el T1d (transfersoma de cianocobalamina) también mostró una atenuación total de la emisión de fotones, lo que sugiere una mitigación eficaz de la infiltración leucocitaria y de su actividad en la zona inflamada. Como se observó anteriormente, las vesículas de transfersomas blancos redujeron los niveles de BLI en comparación con el grupo no tratado, mostrando de nuevo un cierto grado de efecto producido por el vehículo acuoso.

En el estudio histopatológico se compararon las diferencias anatómicas en la estructura de la piel de los animales tratados con transfersomas con los animales sanos y no tratados. Al igual que en el

ensayo de BLI, se observó una clara infiltración celular como respuesta al daño inflamatorio tras la sensibilización con OXA, la cual se revirtió claramente con el tratamiento con transfersomas de cianocobalamina (T1d). Las estimaciones del grosor de los cortes histológicos estimados por medición digital coincidieron con las obtenidas directamente en el procedimiento *in vivo*, y mostraron las mismas tendencias en cuanto a la reducción del grosor. Sin embargo, fue posible observar que este engrosamiento de la piel no está causado únicamente por el edema, ya que la epidermis y la dermis también mostraron un grosor considerablemente mayor en los animales no tratados.

5. Resumen de los aspectos más destacados de la tesis y los hitos alcanzados

Hito 1: Se desarrolló un método analítico de HPLC para detectar y cuantificar la B12.

- Los parámetros calculados demostraron la sensibilidad, exactitud, precisión y robustez del método.
- Los límites de detección y cuantificación del método estuvieron por debajo de las concentraciones habituales de las muestras en los diferentes estudios realizados, por lo que el método analítico fue adecuado para los propósitos de este trabajo.

Hito 2: Se diseñaron, produjeron y caracterizaron tres tipos de vesículas lipídicas: liposomas, transfersomas y etosomas.

- El tamaño y el PDI de las vesículas lipídicas desarrolladas fueron óptimos para fines de administración transdérmica, siendo < 300 nm y < 0,3 respectivamente.
- La flexibilidad de los transfersomas y etosomas fue confirmada por reducción de tamaño y ratios no significativos de pérdida de volumen tras la extrusión en frío.

- La eficiencia de encapsulación obtenida se encontró dentro del intervalo esperado para un fármaco hidrofílico. La carga útil final del fármaco fue inversamente proporcional a la eficiencia de encapsulación.
- Los valores de potencial zeta no fueron predictivos de estabilidad a largo plazo (liposomas < transfersomas < etosomas). Sin embargo, para preservar las vesículas durante largos periodos de tiempo de almacenamiento, se aplicó con éxito la liofilización a los liposomas convencionales y a los transfersomas cuando se utilizó lactosa como agente crioprotector.
- Como consecuencia de la estabilidad de las formulaciones vesiculares a corto plazo, se concluyó que la centrifugación es el método óptimo para purificar los liposomas convencionales, mientras que los transfersomas se purificaron satisfactoriamente mediante diálisis. Por último, los etosomas no se centrifugaron ni se dializaron, ya que, por un lado, no sedimentaron tras la centrifugación y, por otro lado, el etanol puede eliminarse mediante diálisis como consecuencia de su alta afinidad por un medio acuoso.
- Los estudios de liberación concluyeron que, dentro de las 10 h iniciales, la relajación o erosión del sistema vesicular es el principal mecanismo de la liberación. No obstante, la difusión contribuye a la liberación en mayor medida después de este período de tiempo.
- La biocompatibilidad de las vesículas lipídicas se evaluó utilizando la línea celular RAW 264.7. Los etosomas mostraron una alta biocompatibilidad en comparación con los transfersomas, y éstos, a su vez, mayor que los liposomas.

Hito 3: Se diseñaron once prototipos de MNA solubles cargadas con vesículas lipídicas liofilizadas con B12 y B12 libre. PVA y PVP fueron los polímeros utilizados en diferentes concentraciones para producir dichos prototipos. Se elaboraron y caracterizaron con éxito nueve de ellos.

- Las MNA cargadas con vesículas lipídicas mostraron una longitud de las proyecciones más corta que las que incorporaron B12 libre, como resultado de la mayor contracción del polímero por la presencia de la alta proporción de vesículas lipídicas liofilizadas.
- La fuerza mecánica se evaluó a través de la resistencia de las MNA a la compresión, siendo las formulaciones con alta concentración de polímero y combinación PVP-PVA aquellas que mostraron mayor resistencia mecánica.
- Las propiedades de inserción de las MNA en un modelo de piel artificial se correlacionaron con sus propiedades mecánicas, alcanzando una profundidad de al menos 276 μm en todos los casos.
- La liberación del fármaco dependió, en gran medida, del componente polimérico principal de la formulación. Las MNA fabricadas con polímeros de bajo peso molecular (PVA 9-10 kDa y PVP 40 kDa) se disolvieron completamente en la prueba de liberación *in vitro*, mientras que las MNA elaboradas con PVA 38-50 kDa mantuvieron la integridad de la matriz. En consecuencia, los mecanismos que rigen principalmente la liberación son la difusión/disolución y el hinchamiento/relajación de la matriz polimérica, respectivamente.

Hito 4: Las vesículas lipídicas y MNA solubles aumentaron la penetración y permeabilidad de la B12 a través de la piel, que es casi inapreciable cuando el fármaco se administra como solución acuosa.

- La penetración de la B12 mejoró notablemente gracias a las diferentes vesículas lipídicas. Como se esperaba, las cantidades de B12 detectadas en las capas más profundas de la piel aumentan en función del tiempo de incubación y del uso de vesículas ultraflexibles.
- Los resultados de la permeabilidad de la B12 mostraron la misma tendencia que en los estudios de penetración, lo que indica que los

transfersomas y los etosomas son las vesículas más eficientes para transportar el fármaco hasta la dermis, donde puede ser absorbido hacia la circulación sistémica.

- La permeabilidad de B12 a través de la piel aumenta cuando la piel se trata previamente con MNA de tipo sólido. Los microcanales creados en el *estrato córneo* anulan en gran medida su función de barrera y, en consecuencia, aumentan notablemente la tasa de permeabilidad de B12 en las diferentes formulaciones vesiculares.
- Las MNA solubles cargadas con B12 mejoraron también la permeabilidad del fármaco. Los perfiles de absorción mostraron dos etapas diferenciadas. En la primera, el proceso que limita la difusión del fármaco es su liberación de la forma farmacéutica. En la segunda, el perfil de permeabilidad cambia y se alcanza el estado estacionario de la absorción.
- Según los resultados obtenidos, las vesículas lipídicas son los sistemas más adecuados para tratar los trastornos de la piel, mientras que las MNA son ideales para lograr un suministro sistémico de B12.

Hito 5: Los transfersomas cargados con B12 redujeron el edema e inflamación asociada a un modelo *in vivo* murino DTH.

- Los transfersomas cargados con B12 produjeron una reducción significativa de $172 \pm 50 \mu\text{m}$ en el aumento del grosor del pabellón auricular en comparación con el grupo de control no tratado.
- El grupo tratado con transfersomas cargados con B12 no recuperó los niveles basales de grosor de la oreja observados en los controles sanos, pero la diferencia entre los grupos no fue estadísticamente significativa. Estos resultados demuestran que, aunque los transfersomas no pudieron recuperar totalmente el tejido del proceso patológico, contribuyeron a reducir el daño de manera considerable.

- Las formulaciones sin B12 produjeron una reducción no significativa de la variación del grosor de la oreja, probablemente debido a las propiedades emolientes de los lípidos constituyentes de las vesículas y a la capacidad refrescante del vehículo acuoso.
- La implicación de los leucocitos en el proceso patológico desencadenado por la sensibilización con OXA se confirmó mediante el ensayo BLI. El grupo tratado con transfersomas cargados con B12 mostró una mitigación similar a la del grupo tratado con clobetasol. Por su parte, el vehículo sin fármaco también produjo una reducción parcial de la infiltración celular.
- El estudio histopatológico de las secciones de la piel confirmó la disminución del edema, la reducción del engrosamiento de las capas de la piel y el no aumento de la infiltración de leucocitos cuando la dermatitis de contacto se trata con transfersomas cargados con B12.

6. Conclusiones

Las conclusiones más relevantes derivadas de los datos obtenidos en este trabajo son:

- **Conclusión 1:** La B12 puede detectarse y cuantificarse de forma precisa y exacta mediante HPLC y espectrofotometría UV-vis.
- **Conclusión 2:** Las vesículas lipídicas pueden ser producidas y cargadas con B12, y presentar propiedades óptimas para fines de administración tópica y transdérmica.
- **Conclusión 3:** La B12 y las vesículas lipídicas liofilizadas se pueden combinar con éxito con dispositivos de MNA solubles, que presentan propiedades mecánicas y de inserción adecuadas para eludir eficazmente el *estrato córneo* y administrar el fármaco directamente en la dermis.
- **Conclusión 4:** La penetración y la permeabilidad *ex vivo* e *in vitro* de B12 a través de la piel se pueden mejorar considerablemente utilizando sistemas de administración transdérmica: MNA solubles

> combinación de vesículas lipídicas con MNA de tipo sólido > transfersomas > etosomas > liposomas convencionales > solución acuosa

- **Conclusión 5:** La dermatitis de contacto y el eccema pueden mejorarse mediante la administración de transfersomas cargados con B12, que potencian las propiedades neutralizantes del óxido nítrico de la B12 al mejorar su acceso a las capas más profundas de la piel.

Abstract

The bioavailability optimisation of drugs provides them with a second opportunity, which for several reasons, cannot exert an optimal therapeutic effect. This approach is frequently omitted in the pharmaceutical research industry as the discovery of novel therapeutic agents is always more welcome rather than the utilisation of previously available treatments. On this matter, several molecules are rejected as a consequence of the adverse effects they produce when administered systemically or because of their low availability. In consequence, local or organ-targeted therapies have attracted attention as they contribute to overcome these kinds of troubles. The skin has been used as a platform to deliver drugs since ancient times. Nowadays, it is still considered one of the main alternatives to the oral route, as it allows both the treatment of local disorders and systemic drug absorption because of its anatomical structure. However, as an interface between the body and the environment, the outer skin layer (*stratum corneum*) prevents the entrance of substances. This opposition is of major importance for large molecules, and 500 Da is considered the maximum size which can diffuse through the skin structure naturally. Therefore, switching the route of administration is often not enough to solve all the inconveniences mentioned above. Reformulation of drugs in advanced drug delivery systems (ADDS) is commonly needed to bypass the *stratum corneum* barrier and produce an optimised therapeutic effect.

The main objective of this thesis is to develop different ADDS that allow the diffusion of large molecules through the skin. As a model molecule, cyanocobalamin (B12) was selected, due to its high molecular weight (1355 Da) and hydrophobicity, which hinders its transdermal absorption. For this, lipid vesicles and polymeric microneedles were used to encapsulate and increase cyanocobalamin permeability through the skin.

Among all the lipid vesicles developed over the years, conventional liposomes, transfersomes and ethosomes were chosen and characterised towards those properties predictive of an enhanced diffusion. Specifically,

transfersomes and ethosomes showed the best features, as they were homogeneous populations of small size (< 200 nm) and flexible structures. Freeze-drying was used to solve the long-term stability issues that usually affect lipid vesicles, and, as an intermediate step that allows their incorporation in an alternative delivery system, the dissolving microneedles. As microneedles are devices that contain micrometric needle-like projections which bypass the *stratum corneum* directly, they were especially characterised in terms of mechanical strength and insertion capacity. The combination of PVA and PVP polymers conferred the optimal mechanical and insertion properties, as a consequence of the interaction between the hydroxyl and carbonyl functional groups.

In vitro and *ex vivo* studies confirmed the increase in drug absorption when cyanocobalamin was incorporated in the ADDS when compared to a standard aqueous solution, which provided an almost neglectable diffusion. As a consequence of their conception, microneedles were able to deliver the drug transdermally after a moderate period, suggesting their suitability to be used as an alternative to parenteral administration. Lipid vesicles, which showed longer latency times to achieve quantifiable dermal concentrations of drug, were able to localise the drug delivery in the outer skin layers improving the penetration in comparison to the standard solution.

B12 nitric oxide scavenger behaviour makes it possible to ameliorate skin inflammatory disorders such as atopic dermatitis or eczema when applied topically. The feasibility of lipid vesicles for topical treatments was assessed by *in vivo* delayed-type hypersensitivity model. B12-loaded transfersomes significantly reduced the increase in ear thickness in comparison to the untreated group, proving their effectiveness in oedema reduction. In addition, histological findings such as reduced epidermal hyperplasia, dermis thickening, and leukocyte infiltration confirmed the skin restoring effect of transfersomes.

Chapter 1

General introduction: topical and transdermal drug delivery

Chapter adapted from **Skin Drug Delivery Using Lipid Vesicles: A Starting Guideline for the Development of Liposomes, Transfersomes and Ethosomes**. Guillot AJ, Garrigues TM, Melero A. *Submitted to Advanced Drug Delivery Reviews*.

The skin offers a very attractive alternative route for the administration of drugs for several reasons (1). Firstly, it has several advantages over the main delivery routes such as oral or parenteral. Transdermal Delivery of Drugs (TDD) has good acceptance and compliance by patients (2), it is usually painless and does not need aseptic materials, techniques, nor specialised personnel for its administration (3). Secondly, its large surface available -an area of approximately 20.000 cm² in adults- make it the biggest entrance to the body (4). Finally, drug doses can be reduced as the first hepatic passage and the acidic stomachal environment are bypassed, avoiding several undesired effects (5). In comparison, other alternative routes like sublingual, buccal and rectal mucosae have been shown as unpredictable routes with many more limitations (6).

As a result of skin structure, the application of drugs on the skin may have two aims: local therapy or transdermal delivery of drugs (7). The application of a drug onto the skin can pursue different goals: a) remain on the skin to protect the organism or fight against alive entities existent on the skin surface (e.g. sunscreens, repellents or antifungal/antibacterial products) (8); b) treat different skin appendage disorders (antiperspirant or infections) (9); c) treat different affections of the *stratum corneum* and viable epidermis (emollients, exfoliants, anti-inflammatories, antihistaminic drugs, etc.) (10); d) modify the skin barrier function to improve the penetration of other drugs (11); and e) transdermal drug delivery (1).

1.1. A Brief Review of Skin Functions and Structure

For a better comprehension of this chapter, it is essential to define the structure and functions of the skin. The skin is the interface which separates the body and the environment. In consequence, the main function of the skin is to offer a robust barrier against the penetration of external xenobiotics, substances, allergens, and microorganisms (12). In addition, the skin plays other important roles, such as homeostasis maintenance -preventing the dehydration of the body- (13), and protection from the harmful effects of ultraviolet radiation (14). Finally, this tissue presents different types of receptors sensitive to pressure changes, pain and temperature, which are essential to achieve a proper interaction with the environment (15,16).

As mentioned above, the skin is the largest human organ that represents 10% of the total weight. Its thickness varies from 0.05 to 2 mm depending on the anatomical region (17). It can be divided into three differentiated layers: Epidermis, Dermis and Hypodermis.

The Epidermis is the external layer of the skin, and it can be subdivided into four stratum: *basale*, *spinosum*, *granulosum* and *corneum*. The main features of each stratum are summarised in Table 1.1. Keratinocyte is the main cell-type present in the Epidermis layer, it is created in the *stratum basale* and migrates progressively to the next layers, giving rise to a permanent cellular renewal process (18). Keratinocytes are surrounded by a medium with a low content of water. This amount of water decreases as keratinocyte differentiation progresses, and at the end, the most superficial layer is constituted by superposed dead cells -called corneocytes- (19). For drug penetration and transdermal purposes, the *stratum corneum* is the most important layer as it exerts the greatest opposition to drug diffusion through the skin (20).

The Dermis is the vascularised and innervated layer located just below the Epidermis (21,22). It is a network of proteins (mainly elastin and collagen) with notable elastic properties (23–25). Fibroblast (26),

macrophages and leukocytes are the cells present in this layer (27). The irrigation of this layer provides the nutrients to the dermal and epidermal cells and removes metabolites (28). This process allows the systemic absorption of drugs after its administration, since every substance that reaches the dermis microcirculation is susceptible to absorption. The Hypodermis is the deepest skin structure and is often not considered part of the skin. It consists of a matrix made of fatty and connective tissues that connects the skin with underlying tissues and organs (29,30). Its composition and extension vary depending on a range of factors such as gender, age, anatomical site, nutritional conditions and endocrine status (31).

The skin appendages are dermal-associated structures, such as sweat and sebaceous glands, hair and hair follicles (32). All of them are the target of local therapies, for example, acne and alopecia affections (33,34). The transfollicular route has often been ignored because hair follicles only occupy approximately 0.1% of total skin surface (35). It has been demonstrated more recently that hair follicles can have an important impact on the transdermal diffusion of drugs, because their structure offers a thinner barrier between the external environment and dermal microcirculation (36). In this sense, certain types of nanostructures can reach the bottom of the follicle and remain there as a drug deposit (37).

Table 1.1. Main features of the different skin layers.

	Skin Layer	Properties	Function	Ref.
Epidermis	Stratum corneum	-20 to 25 layers of dead and cornified cells	-Prevention of external entities entrance to the body	(20,38)
	Stratum granulosum	-Thin layer composed of keratinocytes which contains keratin granules -Cells are rich in ceramides	-Contains important proteins and enzymes (Filaggrin, Involucrine, Loricrine) -Waterproof task	(39)
	Stratum spinosum	-Thicker layer of cells -Contains Langerhans cells	-Immunological response	(40)
	Stratum basale	-Single layer of keratinocytes which contains stem cells -Contains melanocytes and Merkel cells	-Responsible for keratinocyte division and proliferation (peeling process) -UV protection by melanin production -Sensory perception	(41)
	Dermis	-Fibroblast is the main cell type in this layer -Composed of collagen and elastin -Vascularised and innervated -Location of skin appendages	-Mechanical support of the skin -Contribution to skin elasticity -Supplies nutrients to the dermis -Thermoregulation	(25,26)
	Hypodermis	-Connective and adipose tissue -Not considered part of the skin	-Anchors skin to the different tissues and organs -Protective structure and insulator	(29,30)

1.2. Topical administration of drugs

The access of any substance from the surface to the deeper skin layers follows a passive diffusion process. Two possible routes have been theorised as pathways: the appendageal and the transepidermal routes (Figure 1.1) (42). In the first one, the drug uses the hair follicles and glands to diffuse near the dermal vessels. The main limitation of this route is that those structures represent a minimum proportion of the total skin area and are limited to particles with an appropriate size (< 500 Da) (36,43). The transdermal route is subdivided into two variations: the transcellular route (the molecule passes through the cell and intracellular matrix) and the intercellular route (the molecule diffuses through the lipidic matrix) (44). Although the intercellular path is longer compared to the transcellular one, it is generally accepted as the main route (45).

Figure 1.1. Illustration of the drug diffusion routes through the skin.

This diffusion process is obviously affected by the molecule properties, which conditions its suitability as a candidate for TDD. In these terms, an intermediate partition coefficient between vehicle and membrane (46), a low degree of ionisation (47), and a molecular weight less than 500 Da have been defined as the ideal characteristics (48). Furthermore, the integrity of the skin has a key role in cutaneous absorption, since damaged tissues facilitate the absorption process enormously.

Transdermal absorption of substances is a multistep process, where five stages are distinguished (2): i) Partition of the drug from the vehicle into the *stratum corneum* ii) Penetration of a molecule into the *stratum corneum*; iii) Diffusion from the *stratum corneum* into the viable epidermis; iv) Partition from the viable epidermis to the dermis; v) Access to the systemic circulation. As a consequence of this complex process, it is difficult to suggest a biophysical model that considers all the events involved. Nevertheless, diffusion through the *stratum corneum* or full-thickness epidermis process can be modelled to estimate parameters that characterise the process (49). The typical plot of a permeation study presents two phases: non-steady and steady states (Figure 1.2).

Figure 1.2. Typical plot obtained from a drug permeation through the skin *in vitro* study in Franz diffusion cell set-up, with infinite dose.

Fick's diffusion laws describe the process in the steady state, and they establish that the change of the concentration as function of time is proportional to the gradient variation (2), according to the following equation (equation 1.1):

Equation 1.1:

$$\left(\frac{\delta c}{\delta t}\right) = D \left(\frac{\delta^2 c}{\delta x^2}\right)$$

The Scheuplein equation is an approximation, often used when *in vitro* models are performed under infinite dose and skin conditions. The amount of the drug that diffuses through the barrier is described by the following equation (equation 1.2) (50,51):

Equation 1.2:

$$Q(t) = A \cdot P \cdot L \cdot C \cdot \left[D \cdot \frac{t}{L^2} - \frac{1}{6} - \frac{2}{\pi^2} \cdot \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \cdot \left(\frac{-D \cdot n^2 \cdot \pi^2 \cdot t}{L^2} \right) \right]$$

Where $Q(t)$ is the amount of the drug which diffuses at a given time (t); A is the diffusion surface area (cm^2); P represents the partition coefficient of the permeant between the membrane and the donor vehicle; L is the membrane thickness; D is the diffusion coefficient of the permeant drug in the membrane; and C is the concentration of the permeant ($\mu\text{g/mL}$) in the vehicle (or the donor).

Equation 1.2 can be transformed to determine permeability coefficient (Kp) and lag time (tL) by substituting $P \cdot D/L$ and $L^2/6D$ for Kp and tL , respectively (equation 1.3):

Equation 1.3

$$Q(t) = A \cdot Kp \cdot C \cdot \left[t - tL - \frac{12 \cdot tL}{\pi^2} \cdot \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} \cdot \left(\frac{-n^2 \cdot \pi^2 \cdot t}{6 \cdot tL} \right) \right]$$

The linear regression of the experimental cumulative amount data versus time offers the estimation of Kp and tL . Lag time is calculated as the intercept of the slope to the abscissae axis. Permeability coefficient and maximal flux per surface unit, J_{max} ($\mu\text{g/cm}^2/\text{h}$), can be calculated from the linear regression of the slope according to the equations (equations 1.4 and 1.5):

Equation 1.4:

$$J = \frac{m}{A}$$

Equation 1.5:

$$Kp = \frac{J}{C}$$

Where m is the slope of the linear part from the cumulative amount versus time; A is the diffusion surface area (cm^2); C is the concentration of the drug in the donor drug site.

1.3. Common *in vitro*, *ex vivo* and *in vivo* methods to evaluate drug transdermal permeability and penetration

Even though *in vivo* methods are the ideal procedures to evaluate the effects of any drug delivery system, many studies show that systemic and local drug concentrations can be estimated and predicted using skin permeation parameters, such as the permeability coefficient (Kp), the permeation coefficient (P), the diffusion coefficient (D), the lag time (tL) and the transdermal flux (J_{max}), all of them calculated by *in vitro* and *ex vivo* methods.

1.3.1. *In vitro* methods: Diffusion cells

Since their conception, diffusion cells have become the reference method for assessing transdermal drug permeation parameters. Specifically, Franz diffusion cells (FDC) of static and vertical type are widely used in a huge number of studies (52). FDC are composed of two compartments, also called chambers. They are clamped together incorporating a membrane or tissue in between. The donor chamber harbours the drug formulation, and the receptor chamber is filled with an acceptor medium to receive the drug after its passage through the barrier under study, in this case, the skin (Figure 1.3). To mimic the *in vivo* conditions, as a surrogate method, this receptor compartment is stirred using a magnetic bar and warmed to the physiological temperature of the skin (32-37°C) introducing it in a tempered water bath or using and

additional jacket system surrounding the cell (53). The receptor chamber includes a sampling port that allows the sampling procedure at preset intervals of time. Afterwards, the samples are analysed by a suitable analytical method according to the drug nature and its permeated amounts.

As an essential premise for optimal FDC studies, they should be conducted under conditions that ensure the real performance of the formulations. Finite dose condition is an approach based on the use of an insufficient drug dose that causes a final equilibrium between donor and receptor drug concentrations (54). This method is closer to the *in vivo* and clinic practice conditions. However, it requires complex calculations and complicates the interpretation of the results (55). On the other hand, infinite dose conditions entail the existence of a sufficiently high drug concentration in the donor chamber that produces a concentration gradient between chambers and the maintenance of the skin conditions (56). These conditions ensure a constant thermodynamic dragging force over the drug and results in a practical simplification that makes the perception of the absorption process easier. In these terms, it is accepted that in the acceptor medium, the drug concentration should not increase above 10% of the drug solubility in the medium or decrease beyond 10% of the initial concentration in the donor medium (57,58). However, not only a high drug solubility in the acceptor medium is important towards the maintenance of the sink conditions. Temperature, pH, stirring and degasification have an undeniable influence on the experimental variability. In fact, FDC studies often show a lack of reproducibility, which can be minimised when validated conditions and procedures are followed. Acid or basic drugs solubility is directly correlated with the pH and denotes the importance of selecting the proper acceptor medium to avoid the breakage of sink conditions (57). It has also been reported that an increase in temperature of around 10°C leads to a 2-fold transdermal flux as a consequence of its marked impact in drug diffusivity and solubility (58). Although it seems that stirring and stirrer-type could have a trivial role in the outcome from permeability studies, they determine the correct mixing and homogenization of drug in the receptor

chamber and, hence, the correct sampling procedure and maintenance of the sink conditions. In general, the use of a common magnetic stirrer with a low stirring speed (200 rpm) does not offer proper mixing conditions and higher speed rates are needed (800 rpm) (57). Nevertheless, speeds as high as this can produce air bubbles on top of the receptor chamber that notably reduce the effective diffusional area at the membrane. Therefore, the evaluation of the suitability of the stirrer-speed combination must be assessed in each case, since there are examples where a simple PTFE cylindrical magnetic bar (12x4.5 mm) operating at 200 rpm demonstrated to be optimal (58). As mentioned, degassing must be carried out in any study by tilting the FDC and letting the bubbles come out through the sampling arm, but it must be done as quick as possible in order to avoid temperature fluctuations.

Figure 1.3. Schematic illustration of a jacketed-FDC set-up.

Excised human skin is considered the self-standard as a diffusional barrier for *in vitro* experiments (59). However, ethical and supply issues restrict its use. Moreover, in the case of obtaining human skin samples, they frequently present considerable inter-individual variations, as a consequence of the difficulties to obtain donors with a similar profile (age, gender, ethnic group, general state, etc.) (60–62). Thus, animal skin is used as an alternative, since it is easier to obtain and there is higher homogeneity in the population (62). Porcine skin is, from a histological point of view, the most similar to human (63–65). Rat skin is structurally the most similar

among all rodents, but several studies point that it is more permeable in comparison to human skin (66–68). The thickness of the skin, and particularly the *stratum corneum*, has a notable influence on drug penetration and determination of transdermal absorption parameters (69). This thickness varies depending on the species and the anatomical region chosen, as shown in Table 1.2. Standard experimental protocols and guidelines for *in vitro* skin permeation studies allow the use of full-thickness skin, dermatomed-skin, heat separated epidermis, and *stratum corneum* sheets (59). Heat separated epidermis can be easily obtained by the Kligman method, which consists of plunging the skin for 90-120 sec in a 60°C water bath and then removing the epidermal layer using a forceps (70). For *stratum corneum* layer isolation, the epidermis is immersed for 24 h in a 0.0001% w/v trypsin solution (pH 8.0-8.6) (70).

Table 1.2. Skin thickness among species and anatomical region. Taken and modified from Todo, 2017 (59).

Animal specie	Anatomical region	<i>Stratum corneum</i> (µm)	Epidermis (µm)	Whole skin (µm)
Human	Forearm	17	36	1.5
Pig	Back	26	66	3.4
Pig	Ear	10	50	1.3
Mouse	Back	5	13	0.8
Rat	-	18	32	2.09

Even though *in vitro* permeation through human skin presents high variability in general, animal skin samples are not exempt from it. Artificial cellulose and sulfone based-membranes have been used as diffusional barriers (71–73). Nonetheless, they do not replicate the structure and characteristics of the skin and its use has been relegated to drug delivery mechanistic studies. As a real alternative, reconstructed skin models and 3D-bioprinted tissues have been set-up in recent decades (74). These

artificially generated tissues replicate, either partially or completely (epidermal and dermal layers), the native histological skin structure, but they are rather expensive due to the equipment involved (75). For example, histological architecture is mimicked sandwiching a fibroblast layer between two collagen-based layers and, eventually, including immune cells as well (76). EpiSkin[®], EpiDerm[®] or Labskin[®] are other artificial commercially available skin models.

1.3.2. Ex vivo methods: Tape-stripping, differential-stripping, and confocal laser scanning microscopy

Drug depth-penetration in the skin and dermatopharmacokinetics are usually estimated using *ex vivo* methods (77). Tape-stripping stands out for being a minimally invasive technique that removes the *stratum corneum* (78). Briefly, a skin biopsy is placed onto a glass slide and covered with an aluminium mask, leaving the application area uncovered. A feasible amount of drug formulation is applied, and the set-up is incubated at 32°C for between 2 h and 6 h (79). Longer incubation times can cause the disintegration of the epidermis as a consequence of excessive exposure to occlusive conditions (50). After incubation, 20-25 strips of adhesive tape are applied sequentially to the skin under standardised conditions of pressure to progressively remove the corneocyte layers (Figure 1.4) (80). For this purpose, the percentage of *stratum corneum* removed can be monitored through infrared densitometry devices, differential weighing methods, microscopic measures or transepidermal water loss (TEWL) measurements (80,81). The drug is extracted from the strips, immersing it overnight in an extractive medium where the drug is highly soluble, and then quantified using an appropriate analytical method. To avoid drug concentrations under the quantification limit, strips can be grouped in different pools, for example: 1, 2, 3-5, 6-10, 11-15, 16-20, 21-25. Eventually, tape-stripping can be performed under *in vivo* conditions (82,83). High performance liquid chromatography (HPLC, and UHPLC) (84), Attenuated total Reflection-Fourier transform infrared (ATR-FTIR) (85), Differential scanning calorimetry (DSC) (86,87), and Raman

microscopy have been successfully coupled with tape stripping as analytical methods (88,89). Although the tape-stripping method is widely used to study the barrier activity of skin, it is a technique associated with considerable variability and errors if it is not done under standardised conditions. Therefore, a standardised protocol which specifies the material, pressure, and operating conditions reduces considerably the associated variability (90). Additionally, to reduce the variability, the first strip can be discarded since immediate drug availability in the first layer, or deficient cleaning of the skin surface before the stripping step, can introduce an overestimation (91).

Figure 1.4. Schematic illustration of the tape-stripping technique steps.

Differential-stripping is a technique that consists of a combination of the tape-stripping technique with a cyanoacrylate skin surface biopsy (92). It is considered the most straightforward technique to quantitatively determine the follicular uptake (93). For this technique, human skin is not recommended because hair follicles are contracted after the skin excision. Therefore, pig ear skin is considered here as the gold standard, as the ear cartilage prevents the closure of hair follicles and because they are anatomically quite similar (density and follicular diameter) to human skin (94). Briefly, after carrying out a tape-stripping procedure, as described above, a suitable amount of instant quick-drying cyanoacrylate adhesive is

applied onto the pre-stripped skin (93). Upon the glue polymerisation, the cyanoacrylate layer is peeled off to recover the follicular cast and is then processed similarly to common strips. A mass balance study is highly recommended in both techniques to assure complete drug extraction by the method, where $100 \pm 20\%$ is considered a satisfactory final balance (95).

Confocal laser scanning microscopy (CLSM) has been applied to skin research for multiple purposes, for example, the determination of vesicle pathway, vesicle-skin interactions or the effect of different penetration enhancers (96,97). The CLSM approach is based on linking covalent fluorescent dyes (e.g. rhodamine) to the xenobiotic in order to track the system diffusion (98,99). It allows the virtual depth-sectioning of the skin, slicing horizontal planes, and then reconstructing them to obtain an image of the skin structure (100). The main advantage of CLSM is its low invasiveness (101), and its drawbacks are the interferences as a consequence of skin autofluorescence and short periods of analysis (102).

1.3.3. *In vivo* methods: Microdialysis, skin biopsies, *in vivo* plasma level-time profiles and pharmacodynamic response-correlation studies

Microdialysis (MCD) is the reference method to obtain a complete study of drug pharmacokinetic processes in the skin (103). Unlike the tape-stripping technique, MCD is not only restricted to the *stratum corneum* structure, and *in vivo* conditions provide more realistic outcomes. MCD set-up consists basically of a semipermeable dialysis probe lodged in the skin structure and connected to a perfusion pump, which infuses a physiological receiver fluid (Figure 1.5) (104). The main difficulties of MCD are those related with the surgical procedure to install the dialysis probe (anaesthetic pre-treatment and need of trained personnel) (104), the perfusion conditions like flow or drug concentration in retro-microdialysis (R-MCD) variation (105), the requirement of a highly sensitive analytical method for sample analysis (106), and a compulsory calibration before and after the experiment (107). When an optimal equilibrium of the system is achieved, an exchange of molecules takes place by diffusion, as an effect of the

concentration gradient. The drug molecules, previously released by the drug formulation and permeated until the extracellular fluid in the dermis, diffuse to the receiver fluid and are collected for analysis (108). R-MCD variation uses the same principles, however, the drug under study is dissolved in the perfusion fluid and diffuses from the dialysis probe to the dermis (Figure 1.5) (105). Beyond the information about drug diffusive properties provided by R-MCD, its application seems more limited, as it overlooks the *stratum corneum* effect on drug absorption.

Figure 1.5. Schematic illustration of skin microdialysis and retro-microdialysis basic set-up.

When a drug is applied topically with systemic purposes, *in vivo* plasma concentrations-time profiles offer a direct measurement of the absorption, distribution and elimination processes from blood or plasma samples (109), obtained at pre-set times via tail vein, retro-orbital puncture, jugular cannulation, or other ethically approved bleeding techniques (110). In these experiments, topical formulations are compared to oral, parenteral, or subcutaneous as reference administration routes, to determine the feasibility of topical application as an effective alternative by comparison of certain parameters, such as the area under curve (AUC), maximal plasmatic concentration (C_{max}), time of the peak plasma concentration (T_{max}) and elimination half-life ($t_{1/2}$) (109). Local or systemic

pharmacological effects and safety of topical treatments usually require the use of animal models which trigger the pathologic condition under study. Atopic dermatitis, psoriasis and melanoma models are often employed since there is currently a great interest in these skin diseases (111–113). Diabetes, hypertension and pain are other focus points of pharmaceutical research nowadays (114–116).

The obtention of skin biopsies is an extremely-invasive approach, where skin samples are removed (under anaesthetic procedure) using a punching device or a controlled-deep blade (117). It is used for the study of certain skin affections, such as skin tumours or immuno-inflammatory skin diseases, like atopic dermatitis or psoriasis (118,119). The tissues are further processed to extract the drug and determine drug concentration or the metabolite of interest in the skin. Afterwards, the tissue is homogenised and the drug is extracted from the homogenate to release the interstitial and extracellular analytes (117). Homogenisation is performed usually using either a fast-rotating device that shreds or grinds the skin into smaller pieces or a mortar to pulverise a frozen skin sample (120). Additionally, to ensure a complete release of the intracellular and interstitial content, skin samples can be solubilised using chemical agents (for example hydrogen peroxide 30% and ammonium hydroxide (121), or enzymatic digestion (collagenase) (122). The extraction procedure is performed similarly to the *ex vivo* methods, with a drug-affine medium, or using a precipitation protocol in the case of proteins (123).

Chapter 2

**Motivation and Impact, Aims and
Contributions**

2.1. Motivation and Impact

Cyanocobalamin is a hydro-soluble vitamin (B12) which is stored in the liver and plays important roles in protein metabolism, red blood cell formation and central nervous system homeostasis (Figure 2.1). As a vitamin, it is an essential nutrient that needs to be obtained from the diet, and its deficiency negatively impacts health. On the other hand, its activity as a nitric oxide scavenger has recently drawn attention to it for its potential therapeutic applications.

Figure 2.1. Chemical structure of the cyanocobalamin.

B12 deficiency is the most common cause of certain haematologic pathologies, neuropsychiatric symptoms and other illnesses (124–128). The lack of adenosyl-B12 or methyl-B12 is the usual consequence of vitamin B12 deficiency. It produces impaired methylation processes and methylmalonate metabolism, derived from the amino acids and fatty acids catabolism (129). Low levels of adenosyl-B12, in particular, produce methylmalonic acid accumulation, which can be associated with neurologic syndrome (130). Methyl-B12 deficiency leads to an accumulation of homocysteine, which can induce cellular stress, apoptosis and protein homocysteinylation (128,131).

B12 deficiency has three main aetiologies: autoimmune disorder, malabsorption and low dietetic intake (132). Autoimmune deficiency is a condition in which anti-intrinsic factor antibody production blocks its activity, resulting in an inability to absorb the vitamin (133). The causes of malabsorption are associated with an inefficient production of intrinsic factors by parietal cells in the stomach (134,135). This condition is very frequent in gastric bypass or ileum illness (surgeries, Crohn's disease or *Diphyllobothrium latum* infections) (136–140). Lastly, lifestyles with a growing implantation in society, such as veganism, could lead to a deficiency situation after some years (141–143). Other less frequent conditions like transcobalamin-II genetic deficiency (144), and the use of certain drugs (oral contraceptives, hormonal replacement therapies, metformin, proton pump inhibitors and H2-histaminic antagonists) could also be a cause of B12 deficiency (145,146). Its prevalence in developed areas, such as North America and Europe, varies from 2.9 - 25.7%, depending on the cut-off of the serum level values (<148 and <256 pmol/L of B12, respectively) (129,147,148). Moreover, several studies suggest that it increases with age and is more frequent in women than men (3.3% versus 2.4% respectively, for <148 pmol/L serum levels). Additionally, the impact on developing areas, like Africa, South America and Asia, is significantly higher, and it is not only confined to older age groups, exceeding 40% of prevalence in certain subpopulations (children, young adults and pregnant women) (129).

The management of B12 deficiency depends on different factors like aetiology and severity, and varies as a function of its duration and administration route. It consists of vitamin deposits repletion by intramuscular injections or cyanocobalamin oral doses (149–151). In case of an anomalous functioning of the intrinsic factor way, it is possible to administer 1000 µg of cyanocobalamin by intramuscular injections daily for 1-2 weeks, reduce the posology during the following month to once a week, and continue with a monthly maintenance injection (152,153). However, the intramuscular route presents certain disadvantages, such as: discomfort

and pain generation; the need for aseptic material and techniques; the costs associated with its administration by trained personnel; the restriction to patients with low muscular mass; and medical complications such as thrombus formation, nerves injuries -in femoral and gluteal injections- or hypersensitivity reactions (154–156). As an alternative, it is possible to take cyanocobalamin orally, but the main issues are its low bioavailability (1-4%) and inefficiency in intrinsic factor-related aetiologies (151).

Concerning B12 use as a drug, it has been proposed to treat chronic inflammatory skin diseases. Eczema or atopic dermatitis (AD) and psoriasis are the most common ones, and the molecular mechanisms underneath provide an opportunity for the use of B12 as a possible therapy. AD is characterised by pruritus, dry skin, eczematous injuries and lichenification (157). The onset of AD commonly occurs during childhood, and it is associated with significant morbidity and reduced quality of life. The prevalence of AD has increased over the past 30 years and its incidence has increased two to three-fold in recent years. Approximately 20% of children and 1-3% of adults are affected by this disorder (158). Although the pathogenesis of AD is not completely understood, it has been associated with various factors: alteration of the skin barrier function, immune dysregulation, infections, and environmental processes. The alterations in the skin barrier function may be caused by deficient levels of ceramides and proteins involved in keratinocyte differentiation and prevention of transepidermal water loss (159,160). Several genetic factors, such as mutations in filaggrin genes could cause this situation (161). The defective barrier function allows the penetration of allergens and irritant agents that trigger inflammation through Th2 responses (with increased IL-4, IL-5, IL-13 cytokines) in the acute phase and Th1 responses (with increased IFN-gamma and IL-12) in chronic injuries (162). In addition, the usual action of patients scratching themselves stimulates keratinocytes to release other inflammatory cytokines like TNF-alpha, IL-1, and IL-6, which perpetuate chronic inflammation. Ultimately, the modified state of the skin contributes to bacteria colonisation, which further worsens the disorder (162).

Likewise, psoriasis is a chronic inflammatory skin disease with a marked immune component. Its most characteristic sign is the presence of erythematous plaques, often spread over large areas of the body. The worldwide prevalence varies from 1-8%, depending on geographical areas. Although it can begin at any age, its onset frequently occurs in adulthood, with one out of three cases occurring during childhood (163). A major characteristic in psoriasis pathogenesis is the inappropriate activation of the immune system, which leads to keratinocyte hyperplasia, altered T-cell function, and angiogenesis, among others (164–166). Furthermore, oxidative stress and increased expression of insulin-like growth factor-1 and epidermal growth factor also participate in the pathogenesis (167).

The main goals of the treatment of these pathologies include restoring the skin barrier, limiting itching, decreasing inflammation, and controlling immune alterations. To achieve them, a wide plethora of drugs may be used, with systemic immunosuppressive agents, topical corticosteroids and topical calcineurin inhibitors (TCIs) being the first-line drugs in the pharmacological management of AD and psoriasis (168). However, systemic treatments are not exempt from potential adverse side-effects, such as kidney and liver dysfunction or myelosuppression, which complicate the management of severe cases (169–171). Local side-effects associated with long-term use of topical steroids and TCIs are relatively common, such as skin atrophy, ecchymosis, erosions, striae, delayed wound healing, purpura, easy bruising, and acne (172). In addition, the Food and Drug Administration (FDA) has reported warnings about the use of some TCIs due to the potential risk of skin cancer and lymphomas (173).

The proinflammatory cytokines involved in AD and psoriasis stimulate the expression of inducible nitric oxide synthase (iNOS) in keratinocytes. In consequence, skin lesions of AD and psoriasis present high levels of nitric oxide, which has been implicated in the pathogenesis of atopic eczema and psoriasis (174,175).

Oral and topical B12 have been used as an alternative for preventing or ameliorating AD and psoriasis, since it has been described as a nitric oxide scavenger (176). Although the first trials date back to the 60s, not many studies have been carried out since then (177). Januchowski et al. (2009) compared the effect of B12 cream (0.07%) with a moisturiser base for the treatment of childhood eczema in a double-blinded randomised trial using the SCORAD scale (Scoring of atopic dermatitis). Intraindividual comparisons showed significant differences in reduction of SCORAD values between B12 cream and the placebo. Particularly, topical B12 significantly improved treated skin more than the placebo at 2 and 4 weeks. Recently, mild-to-moderate plaque psoriasis has been treated with topical B12 ointments for 12 weeks in two randomised clinical trials (178). Stücker et al. (2001) compared the effect of B12 with calcipotriol (vitamin D₃ analogue), obtaining similar decreases in the PASI score (Psoriasis Area Severity Index) after the studied period. Moreover, there was a noticeable reduction in the efficacy of calcipotriol after 4 weeks of therapy, whereas the efficacy of B12 remained largely constant over the whole observation period, making it more suitable for long-term use (179). Similarly, a positive outcome was obtained when comparing B12 and an emollient cream in the study done by Del Duca et al. (2017). The differences in PASI reduction were noticeable at week 2 and increased during the following 10 weeks. Two weeks after the end of the treatment, the psoriatic lesions evolved positively (especially the ones treated with B12), proving the potential role of cyanocobalamin-based formulation in the treatment of epidermal disorders (180). Despite these promising results, the molecular weight (1355 Da) and hydrophilicity of B12 limit its diffusion through intact human skin given that one of the main functions of the skin is to prevent the penetration of exogenous substances to the body (181). As the barrier function is recovered during treatment, B12 permeability might be gradually reduced. Research on cutaneous permeability has shown that skin diffusion may be improved by using a suitable formulation, and it can even be used for systemic administration (182).

2.2. Aims

The main objective of this thesis is the development and characterisation of pharmaceutical formulations to enhance B12 penetration and absorption through the skin to offer a feasible alternative in the AD and vitamin B12 deficiency therapies.

To achieve this goal, the project was divided into the following sub-objectives:

Objective 1: Development of an accurate and precise analytical HPLC method for B12 detection and quantification.

Objective 2: Development and characterisation of B12 lipid vesicles (liposomes, transfersomes and ethosomes), emphasising the biocompatibility, stability and other properties that work as predictors of optimal drug penetration and permeability (entrapment efficiency, size, flexibility, and drug release).

Objective 3: Development and characterisation of B12 dissolving microneedles, specially evaluating their cargo delivery properties and ability to overpass the *stratum corneum*.

Objective 4: *Ex vivo* and *In vitro* evaluation of B12 penetration and permeability through the skin provided by lipid vesicles and microneedle arrays, and results comparison with B12-solution as standard reference.

Objective 5: Challenge one of the designed drug delivery systems in an *in vivo* Delayed-type Hypersensitivity (DTH) model of inflammatory skin disease.

2.3. Contributions

During this PhD I have contributed to the field of drug delivery and pharmaceutical technology in the form of research papers, review articles, oral communications, poster presentations, and outreach activities. As part of the “Atracció de Talent” fellowship of the University of Valencia, I have also carried out 240 hours of teaching tasks and actively supervised BSc theses.

Chapter 3

State of the art: lipid vesicles and microneedle arrays.

Chapter adapted from **Skin Drug Delivery Using Lipid Vesicles: A Starting Guideline for the Development of Liposomes, Transfersomes and Ethosomes**. Guillot AJ, Garrigues TM, Melero A. *Submitted to Advanced Drug Delivery Reviews*; and **Microneedle-Based Delivery: An Overview of Current Applications and Trends**, Guillot AJ, Cordeiro AS, Donnelly RF, Montesinos MC, Garrigues TM, Melero A. *Pharmaceutics*, 2020.

When talking about drug delivery via the skin, the most challenging aim from a technological point of view is the achievement of a systemic action. There are several well-known examples of treatments that follow this approach, specifically hormonal (estradiol) (183,184), pain (fentanyl) (185), and smoking cessation (nicotine) therapies (186,187). However, as mentioned before, the main skin function is to prevent the entry of exogenous substances into the body. This barrier function is mainly achieved by the *stratum corneum*, due to its lipophilicity and the great cohesion between the cornified cells (188). Transdermal Delivery Systems (TDS) are a plethora of strategies and resources that aim to increase transdermal drug absorption by modifying the skin barrier function or changing the physicochemical properties of molecules to make them optimal for this goal (189,190). Transdermal drug permeability enhancement can be achieved by two approaches: physical and chemical methods (191). The ideal TDS must present the following properties (44,192,193): a) non-toxic, non-irritant or non-allergenic; b) quick action and predictable duration; c) pharmacologically inert; d) ease removal; e) allow rapid restorage of skin properties after its removal; f) compatible with excipients and drugs; g) comfortable and cosmetically acceptable; and h) inexpensive. Unfortunately, no TDS presents all these properties together to date. The main advantages and disadvantages of TDS are summarised in table 3.1. Nanotechnology aims to develop a huge variety of systems and entities ranging in the nanoscale, from 1 to 1000 nm (194). One of the most important fields of application is nanomedicine, and more specifically, drug delivery (195). In the 1960s, liposomes were designed as nanovehicles with specific programmed functions and precursors of several current nanoparticles (196,197). Not long after, variations in structural components were suggested, as in the case of transfersomes and ethosomes, in order to improve their properties and achieve better results (198,199). Nowadays, these structural variations are still emerging to fulfil the needs and demands of the pharmaceutical industry and the clinical practice (200–202).

Table 3.1. Advantages and Disadvantages of TDS to enhance TDD.

	TDS	Advantages	Disadvantages	Ref.
Chemical methods	Alkanes, Azone, Pyrrolidone, Urea, Fatty acids, Esters, Alcohols, Surfactants, Terpenes	High efficiency in combination with low sized molecules	-Inability to locate their effects only on the <i>stratum corneum</i> -Skin reactions (irritation, inflammation, and erythema) -Low efficiency in combination with macromolecules	(203–205)
	Prodrugs	-Higher drug stability -No degradation in the skin	Size increase can reduce its permeability through the skin	(42,206)
Physical methods	Iontophoresis, Sonophoresis, Electroporation and thermal methods	-Rapidly responsive molecular transport -Control of transport magnitude	-Expensive devices -Inability to locate the effects only on the <i>stratum corneum</i> -Intense skin reactions (irritation, inflammation, and erythema)	(207–211)
	Jet Injectors	-Control of drug depth deposition	-Possible incorrect dosage and skin damage, pain, and infections	(212,213)
	Microneedles	Bypass the <i>stratum corneum</i>	-Expensive production compared to other methods -Difficult use for local skin treatments -Time that micropores remains open still unclear	(214,215)
	Microsystems and Nanosystems	Possibility to achieve drug release in the first layers of the skin or a transdermal drug delivery	High-sized systems cannot improve drug diffusion through the skin	(216)

3.1. Lipid vesicles: Liposomes, Transfersomes and Ethosomes

Lipid vesicles are non-toxic and biodegradable biomembranes obtained artificially, that have gradually evolved over time and been successfully applied as drug carriers for controlled, targeted, and enhanced drug delivery (217). Their application to TDD is highly attractive, because their lipophilic nature allows them to incorporate poorly soluble drugs in aqueous media and improve the penetration properties of drugs through the skin (218,219). Other advantages have also been documented, such as increased stability of photosensitive molecules (220), lower drug degradation (221), and depot release (222).

3.1.1. Composition and structure of Lipid-based vehicles

3.1.1.1. Components of lipid vesicles for transdermal delivery of drugs

Liposomes, transfersomes and ethosomes are mainly composed of phospholipids, and they present a lipid bilayer structure, similar to cellular membranes (223). The amphiphilic character of phospholipids, as a result of their hydrophobic tails and hydrophilic heads, allow them to spontaneously disperse in aqueous medium and incorporate both hydrophilic and lipophilic drugs (Figure 3.1) (224). Variations in polar head and nonpolar tail functional groups lead to a broad variety of phospholipids that can be used in vesicles production. Phosphatidic acids (DMPA, DPPA, DSPA and DMPG), Phosphatidyl glycerols (DPPG, DSPG, POPG, DMPE), Phosphatidyl ethanolamines (DPPE, DSPE, DOPE, DLPC) and Phosphatidyl cholines (DMPC, DPPC, DSPC, DOPC) are the common types used in drug delivery, which condition to a certain degree the properties of the developed systems (225). For example, phosphatidyl cholines tend to form permeable, but less stable, bilayers, whereas acyl chains-based phospholipids form more stable bilayers but more rigid structures (226). Lipid vesicle composition often includes stabilising agents to produce systems like cell bilayers, with cholesterol being the stabiliser *par excellence*. The phospholipid/cholesterol ratio varies from 0 to 25% w/w and depends on the vesicle application purposes (227). On one hand, it is

well documented that the entrapment efficiency of lipophilic drugs decreases if the percentage of cholesterol increases, since they occupy the same space in the lipid bilayers (228). On the other hand, the increase in cholesterol content produces an increase of vesicle size and Polydispersity Index (PDI), probably as a consequence of the capacity of stabilising higher structures (227). Finally, cholesterol can influence vesicle rigidity and, consequently, drug release and leakage. In general, the higher the cholesterol content, the higher the bilayer rigidity and lower the vesicle flexibility (229), and therefore the more flexible the vesicles, the higher the drug release and leakage (79).

The other key factor for deformability of the lipid vesicles is to include edge-activators in their composition, which leads to the obtention of transfersomes (230). The most common edge-activators are surfactants: tweens[®], spans[®], bile salts (sodium cholate and sodium deoxycholate), and dipotassium glycyrrhizinate (230–233). Usually, those components are a single chain surfactant which causes a destabilisation of the lipid bilayers and increases its fluidity and elasticity by lowering the interfacial tension (234). These surfactants produce micelles if they are present in concentrations greater than the micellar critic concentration (235). However, when the molar relation phospholipid/surfactant is optimal, which happens at low surfactant concentrations, they are incorporated in the lipid vesicle structure, conferring interesting properties to the ultraflexible or ultradeformable vesicles. For instance, 15% w/w has been revealed to be the more efficient proportion in the case of non-ionic surfactants as tween or span for transdermal delivery purposes (236,237). In addition, 25% w/w seems the most appropriate concentration in the case of sodium deoxycholate (237).

Ethosomal systems are composed of phospholipids, water, and ethanol, or other volatile alcohols at high concentrations (up to 50% w/w) (238). However, the most suitable concentration of ethanol would range between 20-30% w/w to ensure the formation of closed multilamellar

vesicles with good transdermal delivery results (199). Characterisation properties are also affected since size decreases with the increase in ethanol concentration (239).

The new designs of lipid vesicles are based on the incorporation of other components in an attempt to give additional properties to the formulations. Glycerosomes are vesicles with considerable amounts of glycerol (10-30% in the water phase) (240). Their objective is to confer extra flexibility to the bilayers and hydrate the skin at the same time, due to the humectant properties of glycerol (241). Inspired by the features that hydrogels can offer to liposome delivery, such as an extra control of release, hyaluronosomes aim to incorporate a gelled nucleus made of hyaluronic acid, avoiding the possible inconveniences that polymeric matrices could produce, like an excessive retention of active ingredients or long-term stability issues (242).

3.1.1.2. Structure of lipid vesicles and classification

Depending on the production method and composition, it is possible to obtain different types of lipid vesicles. According to the superficial charge given by the phospholipids, they can be classified as anionic, cationic, or neutral vesicles (243,244). Moreover, the size and number of lipid bilayers are the usual parameters to characterise them. Multilamellar vesicles (MLV) are those that present more than one bilayer, which enclose the same number of aqueous compartments. Unilamellar vesicles have just one bilayer and a central aqueous core (245). These well-differentiated environments make lipid vesicles a versatile TDS, as they can shelter drugs dissolved in the aqueous core or inserted within the lipid bilayer structure (Figure 3.1) (246). MLV are usually bigger in size, ranging between the nanometric scale up to 1 μm . When the number of bilayers is less than 4, they are called oligolamellar vesicles, and the drug entrapment efficiency is commonly higher than MLV (247,248). A special case is multivesicular vesicles, where a large bilayer confines multiple vesicles inside it (MVV) (249). Unilamellar vesicles are subclassified as small unilamellar vesicles

(SUV) and large unilamellar vesicles (LUV). SUV present a size lower than 100 nm, spherical shape and a homogeneous size distribution (250). The entrapment efficiency of hydrophilic drugs is limited. On the contrary, LUV are larger vesicles (100-1000 nm) with a bigger aqueous core, which increases the capacity of encapsulating hydrophilic molecules (251).

Figure 3.1. Lipid vesicle classification according to size and number of lipid bilayers. Location of liposomes, transfersomes or ethosomes components in the lipid vesicle structure.

3.1.2. Mechanisms of action of liposomes and ultraflexible vesicles

It has been reported that liposomes can effectively interact with cells by different methods (252): a) absorption by specific interaction with cell-surface components, electrostatic and hydrophobic forces, b) endocytosis by phagocytic cells like macrophages and neutrophils; c) fusion and cytoplasm delivery by insertion of liposome bilayers into cell membranes; and d) exchange of bilayers components.

However, the mechanisms of action when applied on the skin for transdermal delivery purposes remain unclear. It is generally accepted that conventional liposomes fail to penetrate the skin layers and remain on the skin surface (253), acting as a kind of depot formulation (254). The liposomes could directly interact with the skin and exchange the drug by the “collision complex transfer process” observed in other biological systems,

or could release the free drug which is available to penetrate through the skin (255). In the last case, liposomes perform not only a depot function, but they can induce structural changes in the *stratum corneum*, thus facilitating the drug absorption (256–258). In the same way, a very similar mechanism based on the liposome insertion into the outer lipid layers of the *stratum corneum* can also explain the enhancement effect (98). All these theories exclude the penetration of the intact liposome structure, which has been extensively assessed in different studies. For example, Dreier et al. (2016) combined the stimulated emission depletion microscopy (STED) and raster image correlation spectroscopy (RICS) to study the mechanism of action of conventional liposomes once applied to the skin. The images of tissue samples incubated with radio-labelled liposomes, obtained by skin cryo-section, revealed that liposomes do not remain intact beneath the skin surface and suggest that the liposomes do not act as carriers that transport their cargo directly through the skin barrier (259). This poor performance of conventional liposomes has also been observed when crossing other biological barriers, such as the intestinal epithelia (260). In Dreier's et al. (2016) study, the penetration of conventional liposomes was compared to sodium cholate-based vesicles. As expected, the conclusion points out that fluorescent-labelled ultraflexible vesicles were able to deliver their content deeply. The improvement in the delivery obtained from transfersomes supports the existence of extra mechanisms involved for transfersomes. From its conception, transfersomes designers support that they can pass through the skin in a squeezing process helped by an osmotic gradient as a driving force, created by the difference in the water concentration between the skin surface (near to 15% in *stratum corneum*) and the viable epidermis layers (around 75%) (198). Specifically, this skin environment is strong enough to push between 0.1-0.5 mg of lipidic material per hour and cm², which is substantially higher than the typical flux produced by concentration gradients (198,261). As may occur with liposomes, the exact mechanism of transfersomes is the result of the combination of drug vectorisation, *stratum corneum* disruption and penetration features of transfersome vesicles,

bearing in mind that the destabilisation of *stratum corneum* produced by transfersomes is more intense due to the action of surfactants incorporated in the vesicles. One confirmation of these squeeze-mediated mechanisms is the study done by Cevc et al. (2002) (96). In their study they assessed the fracture of liposomes during the transport through a semipermeable barrier, while transfersomes maintained their initial sizes. They also present the liposome and transfersome behaviour after its application on a murine skin model using CLSM, and confirmed the presence of intact vesicles in the blood stream of transfersome-treated mice by size exclusion chromatography. Similar findings have been obtained in several studies performed by other researchers in different types of ultraflexible vesicles, as Niu et al. (2019) and Manconi et al. (2011) (102,262).

Ethosomes are considered a variation of transfersomes because they have the same ability to penetrate intact through the epidermal layers. The underlying mechanisms of action are essentially similar, with little differences. Besides being a bilayer fluidiser, ethanol is also a chemical enhancer that promotes *stratum corneum* disruption by its interaction with the polar groups of skin phospholipids (263,264). Nevertheless, it has been reported that the enhancement produced by an ethosomal formulation is greater than those produced by ethanolic drug solutions (265,266). Moreover, the ethanol evaporation once applied on the skin surface could increase the effect of concentration gradient in the transdermal absorption process.

3.1.3. Production methods of lipid vesicles

A wide variety of lipid vesicle preparation methods are available, and each of them has certain advantages and disadvantages, and confer specific characteristics to the vesicles (267). Its selection depends on different parameters, such as: a) physicochemical properties of the encapsulated drug and lipid vesicle components; b) effective therapeutic drug concentration and its toxicity; c) desired vesicle size, polydispersity

index and surface charge according to its further applications; and d) batch reproducibility and scale up production.

3.1.3.1. Liposomes and Transfersomes production methods

The specific molecular mechanism of liposome formation depends to a large extent on the production method used. The basic underlying principle is the hydrophobic/hydrophilic interactions between lipid and water molecules, regardless of the chosen methodology (268). The application and transference of energy in form of heating, stirring, shaking or sonication contributes to the arrangement of the lipid molecules into bilayer vesicles.

The Bangham's method, also known as film method, is the first described procedure to obtain lipid vesicles (196). It presents three clear steps, consisting of the preparation a phospholipid/cholesterol/edge activator organic mixture; removal of organic solvent using a rotary evaporator to produce a thin-film on the round-bottom flask wall; re-hydration with an aqueous solution above the phospholipid transition temperature to produce the lipid vesicles. Despite the method simplicity, the low entrapment efficiency in many cases, and the production of MLV heterogeneous populations makes further procedures to obtain useful lipid vesicles for transdermal purposes necessary (269). Furthermore, different methods have emerged over the years to overcome the limitations of the original method (Table 3.2).

3.1.3.2. Ethosome production methods

Touitou et al. (2000) introduced for the first time a lipid vesicle with ethanol as an edge-activator (199). The proposed method consists of preparing a 20-50% w/w ethanolic phase at 30°C and stirred at 700 rpm and its dropwise addition into an aqueous phase, using a constant rate of 12 ± 0.5 mL/h. The incorporation of the active ingredients can be done in the organic blend or in the aqueous solution, depending on its physicochemical properties. Then, when the proper volume of water is incorporated, the ethosomal dispersion is kept under stirring for 5 min and

homogenised in terms of size and PDI by different methods. This procedure is defined as a classical cold method, and one of its main advantages is that it is done almost at room temperature, so it allows the preparation of thermo-sensitive drug-loaded lipid vesicles (263). Alternative methods can be used to produce ethosomes in a more efficient way (Table 3.2), as it is for conventional lipid vesicles.

Table 3.2. Main lipid vesicle production methods.

Method	Procedure	Outcome	Ref.
Thin-Film (Bangham's method)	It can be used for preparing ethosomes if the thin-film is rehydrated with an ethanolic solution	MLV	(270)
Ultrasonication	Strong ultrasound pulses applied to an aqueous phospholipid dispersion	SUV LUV	(271)
Reverse-phase evaporation	Phospholipids are hydrated by mixing the aqueous and organic phases. When organic solvent is removed, a gel is produced, which turns into a vesicle dispersion	MLV LUV	(247,252, 272)
Eter/Ethanol injection	Phospholipids are dissolved in an organic phase which is injected through a syringe system into the aqueous phase	SUV LUV	(273,274)
Hot method	Drug is dissolved in ethanol and propylene glycol mixture. Then it is added to a 40°C phospholipid aqueous dispersion and mixed for 5 min.	SUV LUV	(275)

3.1.4. Purification methods of lipid vesicles

A mandatory step in the production process to obtain homogeneous final products is to remove the excess of vesicle components (252). In addition, the elimination of non-entrapped drug fraction, these purification methods can remove the rest of non-incorporated components guaranteeing a high-quality formulation (276). As the molecular weight of lipid vesicles is considerably higher than drugs and edge-activators, most of the methods are based on this size difference.

Even though these methods allow the vesicles purification, they have drawbacks in most cases, such as vesicle dilution or decreased product yield (277). These difficulties explain why large-scale purification is limited and the purification process remains nowadays a challenge. According to the drug physicochemical properties and lipid vesicle final application, researchers must choose the appropriate method in each case. The most used purification methods are dialysis, centrifugation, ultrafiltration, and size exclusion chromatography (Figure 3.2).

3.1.4.1. Dialysis method

Dialysis removes non-entrapped molecules from liposomal dispersions with the use of a semi-permeable membrane, whose pores allow molecules to pass through, while the diffusion of large structures is restricted (278). The simplicity of the process, the possibility to purify large volumes of vesicle formulations and its low cost are the main advantages of this technique. The success of this method resides in the use of an appropriate dialysis bag and dialysis media. Both free drug and other molecules should be highly soluble in the dialysis media for an adequate extraction (279). Moreover, osmotic pressure must be considered to preserve the vesicles' integrity and avoid the forced leakage of entrapped drugs (227). This operation is generally successful for hydrophilic molecules, since an aqueous media generally fulfils these requirements, and it is usually performed at low temperatures, around 4°C (79,280,281). The time required to complete the process is one of the main disadvantages

of this method, as it takes at least 24 h to ensure complete free-drug removal (79,280). However, an excessive dialysis time can lead to an encapsulated drug depletion as a consequence of the drug affinity for the media (282). Dialysis of lipophilic molecules is often more complex as drugs do not pass to aqueous media, and double-way flow of organic media through the pores in the diffusion process could make the vesicle structure unstable. Nevertheless, if the volume ratio between vesicle dispersion and aqueous dialysis media is considerably balanced in favour of the media, the concentration gradient for drug diffusion remains active and the dialysis of lipophilic components is possible (281).

3.1.4.2. Centrifugation method

The application of a centrifugal force to heterogeneous dispersion produces the separation of its components according to their size and density. It can be used in lipid vesicle purification, leveraging the obvious differences regarding size, weight and density between non-encapsulated components and lipid vesicles. Under the centrifugal force, free drugs remain in the supernatant, while lipid vesicles tend to accumulate in the bottom of the centrifuge tube or Eppendorf. The optimal rotor speed depends on different factors, such as the density of the medium or vesicles size and stability, but as a general rule, the rotating speed to achieve an effective separation should be up to 10000 rpm and applied between 30-90 min at 4°C (79,283,284). Differential high-speed centrifugation precipitates vesicles under forces up to 100000 xg. However, excessive forces may cause particle aggregation and the bilayer fusion, with the subsequent drug entrapment loss.

3.1.4.3. Ultrafiltration method

Ultrafiltration is a method that combines the centrifugation and the pass of free molecules through a semipermeable membrane (285). As with dialysis, the pore size plays a key role in the purification process. Usually, to achieve an effective purification, the pore size used is ranged at least one tenth of the vesicle size (between 50-300 kDa) (285–288), and

centrifugation force around 4000 rpm or 2000 xg (286,287,289). High weight structures are retained in the membrane while water and other smaller components freely pass through the membrane pores. The method divides the formulation in two fractions: the ultrafiltrate which contains the extra-vesicle components in the vesicle dispersion medium, and the sediment which contains the lipid vesicles (286). Thus, ultrafiltration is especially useful for hydrophilic drugs and its main advantages are that drug leakage is partially avoided as the liposomes do not immerse in a purification media, and it reduces the time to complete the purification (around 1-2 h) in comparison with the dialysis method (288).

3.1.4.4. Size exclusion chromatography method

Size exclusion chromatography is based on the separation of the components of a blend as a consequence of their interaction with the porous beads contained in chromatographic columns, which leads to a different retention time (290). The non-entrapped drug and other free components with low molecular weight and size are capable of interacting with the pores, whereas lipid vesicles or other large components do not enter the pores (291,292). Consequently, the elution of vesicles is relatively quick, while the free drug is retained in the column for a longer period. To achieve an efficient elution, the type and diameter of gel particles and pores is essential. Sephadex, Sepharose and Sephacryl columns are the most used. For example, Sephadex G-25, G-50 and G-100; Sepharose 2B, 4B and 6B; and Sephacryl S200 and S1000 usually offer good results in liposomes purification (252,276,291,293,294). The time needed to complete the purification process is intermediate, no more than 6 h (276). The inconveniences of this method are possible reactions between vesicles and reactive groups of gel particles, drug leakage (286), and issues in removing lipophilic compounds as the eluent solutions are usually of a hydrophilic character, like HEPES buffer (295).

Figure 3.2. Purification methods of lipid vesicles: dialysis, centrifugation, filtration and size exclusion chromatography.

3.1.5. Size reduction procedures of lipid vesicles

MLV formation is often spontaneous after using most of the lipid vesicle production methods (296,297). Nevertheless, the topical and transdermal application mostly requires the use of vesicles with a smaller and specific size (SUV and LUV). The reduction of the size and lamellarity is possible once the vesicles are obtained by different methods. Usually, the techniques used for those purposes are sonication, extrusion, and homogenisation.

Lipid bilayers present different structural states depending on the temperature (298). There is an ordered phase, also called gel state, which exhibits high rigidity at lower temperatures. On the other hand, beyond the transition phase temperature, which is specific for each lipid type, they become a disordered phase, known as liquid-crystalline state. At this phase, lipids have soft mechanical properties making the bilayers more fluid (298,299). In that way, it is important to work above the phospholipid transition temperature (298,300), while reducing size vesicles, to prevent a sharp drop in the efficiency process (301).

3.1.5.1. Sonication

Sonication provides energy to the vesicle systems by high frequency ultrasound. Usually, it allows the obtention of a homogeneous population of SUV from the sonicated MLV (302). The obtained SUV show a size not larger than 200-100 nm (303,304). In particular, ultrasounds can be applied in short intervals (around 30 sec) or pulses of a few seconds to the vesicles (303–306). The number of pulses (from 3 to 8 cycles) depends on their energy and frequency (ranging up to 600W and 450kHz) (303,306,307). The main limitations of the sonication technique are the oxidative reactions that phospholipids could suffer and the loss of encapsulated drugs, especially if they are hydrophilic, as a result of the reduced aqueous volume entrapped within the bilayers (247).

3.1.5.2. Extrusion

Extrusion converts MLV into homogeneous LUV and SUV vesicle populations (308,309). The technique consists in the passage of the vesicle dispersion through polycarbonate or polyethersulfone extrusion membranes with uniform pore networks (310–313). The pore size ranges usually between 0.1 and 5 μm (309,311,313). Variables that define the lower size attainable are pore size, number of extrusion cycles, applied pressure, extrusion temperature and vesicle flexibility (313). Different protocols have been proposed, but around 20 passages, combined with the appropriate extrusion membranes, have commonly been performed to

achieve sizes lower than 300 nm (281,314). However, Ribeiro et al. (2018) demonstrated that after 6 passages, the particle size of liposomes was reduced significantly from 569 ± 61.2 nm to 162.5 ± 1.4 nm, accompanied with a reduced PDI lower than 0.150 (308).

3.1.5.3. Industrial methods

Homogenisation, French press, and micro-fluidification methods can be considered an evolution of the extrusion technique. They are the preferred methods in the industrial context (301). Operating at high pressure levels, the first two consist of pumping the vesicle formulation through a stainless holed wall, while a microfluidiser aims to provoke vesicle collisions between them (315–318). The main drawbacks of all of them is their own working high pressure and the equipment costs, but on the other hand, the reproducibility in downsizing and the possibility of processing higher vesicle formulation volumes makes them ideal methods for scale-up process (301).

3.1.6. Drug-loading strategies

Drug encapsulation in lipid vesicles is probably one of the critical steps in vesicle production, as their pharmacological activity is subjected to achieve drug concentrations within the therapeutic range after the drug release process. Two loading strategies can be distinguished: active and passive loading.

Passive strategies just rely on the spontaneous capacity of vesicles to capture a certain aqueous volume (where a water-soluble molecule is dissolved) during their formation (319,320). As hydrophilic drugs are located in aqueous core of vesicles, their entrapment efficiency is affected by the vesicle size and lamellarity, and these, in turn, by phospholipid concentration and production methods (321). Regarding lipophilic molecules that are embedded within the lipid bilayer, the entrapment efficiency mainly depends on phospholipid concentration and vesicle number, regardless of the size or morphology (322).

Active loading consists of the incubation of empty vesicles with a drug solution to push the cargo through bilayers if they are permeable enough. In the simplest case, a concentration gradient is the pushing force to complete the loading until the equilibrium between the interior of vesicles and the surrounding medium is achieved (323). In consequence, this type of loading is restricted to hydrophilic and small molecules, with the packaging structure of bilayer components being the main opposition to the loading (324). Efficient and quick loadings can be achieved using other pushing impulses, such as pH gradient (325). It involves the preparation of liposomes using a pH buffer around 4.0 and then adjusting the external pH to more than 7.0, adding a basic character compound or directly exchanging the surrounding medium by the optimal buffer solution (326).

Freeze-thaw cycles is also a processing technique to encapsulate drugs into vesicles or to improve the entrapment efficiency (327,328). It works as an extra force to achieve the equilibrium in drug concentrations inside and outside the vesicles (329). The optimal number of freeze-thaw cycles reported in the literature is highly variable (up to 10 in some cases) (330), because of the different types of drugs involved. Zhao et al. (2009) showed that 4 cycles are optimal in the case of protein-loaded vesicles (331). However, Costa et al. (2014) reported that 2 freeze-thaw cycles resulted in the maximum predicted entrapment efficiency of Tenofovir, a polar anti-HIV nucleoside with low permeability (329).

3.1.6. Key properties and parameters in the design of lipid vesicles for transdermal delivery purposes

In order to achieve a highly efficient transdermal permeability of drugs, lipid vesicles should present some key properties, namely: size, morphology, PDI, zeta-potential, entrapment efficiency, deformability degree, drug release properties, stability, and biocompatibility. These properties are connected with each other, and therefore, changes in one of them lead to variations in the other. Consequently, it seems almost impossible to get the perfect or ideal vesicle and the real challenge focuses

on the development of a prototype with a suitable balance between all the key parameters.

3.1.6.1. Entrapment efficiency

The drug-to-lipid ratio influences the drug therapeutic index for any lipid vesicles application (332,333). Hence, high entrapment efficiencies are desirable since they contribute directly to achieving significant effects after vesicles administration. In turn, entrapment efficiency is dependent on various factors such as physicochemical properties of drugs, vesicle size and lamellarity, and vesicle production method.

Firstly, hydrophilicity or lipophilicity of drugs have a huge influence in the encapsulation process when vesicles are loaded through passive strategies. Lipophilic drugs attain a high encapsulation ratio, around 90% or above, as a consequence of their intercalated location between lipids of vesicle bilayers, while hydrophilic drugs present low entrapment rates, between 10-50% (334–336). Encapsulation of water-soluble drugs depends on the fact that an important proportion of drug dissolved into the water phase remains outside the vesicles, decreasing the encapsulation ratio. This is the reason why size conditions, especially the entrapment efficiency of water-soluble drugs: LUV, in comparison to SUV, have larger amounts of water in their core (272). In the same way, the increase in the number of lipid bilayers in MLV plays in favour of lipophilic drug entrapment, as the concentric membranes increase the available space for hydrophobic drugs. Moreover, MLV also improve encapsulation of hydrophilic drugs since the several bilayers tend to retain inside this type of drugs (321).

Secondly, as each production method provides different types of vesicles regarding size, it can be considered that the entrapment efficiency is also subjected to the selection of the manufacturing technique (337).

Finally, the drug loading method is the last factor which has a notable influence on entrapment efficiency. Active loading strategies have an excellent uptake response from vesicles which can improve the entrapment

efficiency, since it is independent of the lipid composition and presents high drug retention properties (338).

Entrapment efficiency can be directly or indirectly calculated. The indirect method consists of determining the amount of drug present in the outer medium of vesicles to estimate the entrapped fraction of drug by difference to the initial amount of drug formulated (339). For this, usually vesicle dispersions are centrifuged to isolate them and analyse the supernatant, which contains the non-entrapped drug fraction (339). The direct estimation of the entrapped amount of drug requires the destabilisation of vesicles to force the release of their content (340). It is achieved by adding high amounts of methanol or surfactants like sodium dodecyl sulphate or Triton X-100 (79,334,340,341).

3.1.6.2. Determination of phospholipid concentration

The efficiency of lipid vesicle fabrication and their percentage in phospholipids in establishing the drug-to-lipid ratio can be estimated through different methods (342). Chemical methods like Steward, Rouser and Bartlett assays are frequently used, as they are relatively simple and cost-effective. In Steward's assay, the vesicle solutions are mixed with chloroform, FeCl_3 0.1 M, NH_4SCN 0.4 M in a ratio 0.5:3:2:2 and vortexed for 20 s. After centrifugation (1000 rpm) for 5 min, 2 mL of the lower chloroform fraction is carefully transferred into a quartz cuvette, and absorbance is measured at 485 nm (343). Rouser's method consists of heating 100 μL of vesicle solutions at 270°C until complete liquid evaporation, followed by the addition of 450 μL of HClO_4 (70% v/v). After, the blend is heated to 250°C for 30 min. Then, 3.5 mL of water, 500 μL of ammonium molybdate (2.5% w/v) and 500 μL of ascorbic acid (10% w/v) are added. Finally, the mixture is vortexed and incubated at 100°C for 7 min and cooled down again. The absorbance is measured at 820 nm (344). In Bartlett's method, up to 2 mL of samples and 0.5 mL of H_2SO_4 10 N are mixed and heated at 150-160°C for at least 3 h. Subsequently, 2 drops of H_2O_2 (30%) are added and maintained at 150-160°C again for 1.5 h to

ensure a complete combustion and decomposition of all the peroxide. Then, 4.6 mL of ammonium molybdate (0.22% w/v) or 4.4 mL of water, plus 0.2 mL of ammonium molybdate (5% w/v) and 0.2 mL of Fiske-SubbaRow reagent are added, mixed, and heated for 7 min in a boiling water bath. The optical density is measured at 830 nm (345).

Alternatively, enzymatic assays have been suggested to determine phosphatidylcholines in liposomes (346). For example, a colouring reagent solution is prepared by adding 45 mL of buffer solution (Tris buffer 50 mM, calcium chloride 5 mg/dL, and phenol 0.05%) to the dry colouring reagent (phospholipase D 20 U, choline oxidase 90 U, peroxidase 240 U, 4-aminoantipyrine). Microwell plates are filled with 50 µL of vesicle dispersion and 250 µL of the colouring agent and warmed to 37°C for 5 minutes. The quantification is performed measuring the absorption at 492 nm. Other techniques have seldom been applied based on phospholipid and its degradation product determination purposes, such as gravimetric assays (347), magnetic resonance spectroscopy (H-RMN) (343), and ultra-high-performance liquid chromatography-mass spectrometry (UHPLC-MS) (348).

3.1.6.3. Size and morphology

The particle size of lipid vesicles is probably one of the parameters with a stronger influence on the transdermal delivery. Generally, the smaller the vesicles, the higher the transdermal flux is achieved, even though it is dependent on other parameters (349). Vesicles with a diameter of 300 nm or below enable the delivery of their 'cargo' to the deeper skin layers, especially when they are flexible. Verma et al. (2003) used CLSM to visualise the effect of the size penetration ability of liposomes, loaded with the fluorescent molecule. The maximum levels of fluorescence in the cryo-sectioned skin samples were observed with < 70 nm diameter, while liposomes with a size of 120 nm diameter also showed statistically enhanced skin penetration as compared to larger ones (350). On the contrary, vesicles sized 600 nm or above remain on the *stratum corneum*

layers where they release their cargo (351,352). Absorption through the skin of vesicles ranging between 200-600 nm is possible, but their performance is more influenced by other aspects, such as edge-activators composition or the deformable behaviour of vesicles (353).

The exact mechanism that nanovesicles follow in the skin permeability process is still under discussion, however, it also seems to be linked to vesicles size. Small nanovesicles may be absorbed through transepidermal routes including aqueous pores (354), whereas larger entities up to 210 nm also follow the transfollicular route as an extra option (43,355). As mentioned before, size and morphology can be controlled choosing the appropriate vesicle production method, and are commonly assessed by Dynamic Light Scattering (DLS) and microscopy techniques respectively (356,357).

DLS is a reliable method for determining the size of nano and micro particles (308,358). It is based on the property of vesicle dispersions to produce a variable light scattering over time because of the constant changing position of vesicles as result of a Brownian motion. DLS measures this intensity and its fluctuations to establish a correlation function. An exponentially decaying function is correlated with decay times, which are related to diffusion coefficients and particle radius by the Stokes-Einstein equation (359).

Microscopy techniques offer the possibility to visualise the lipid vesicles and estimate their preliminary size. These techniques are not a surrogate of DLS since vesicles can show certain variations in size due to the sample preparation protocol. Optical microscopy is a basic tool unable to provide complete information about lipid vesicles and their bilayer in comparison with other microscopy techniques (360). Nevertheless, it can be used to obtain a quick image of lipid vesicles and general information, although not precise, about the size, shape, and homogeneity of big vesicle types such as Giant Unilamellar Vesicles (GUV) and even MLV (361–363).

Electron microscopy is the most extended method for the visualisation of lipid vesicles. It offers a high magnification and super-resolution images that allow us to obtain a clear view of vesicles (364). This technique focuses a beam of electrons onto the vesicles' surface, which are scattered by the sample. These electrons are refocused and magnified to produce a projected image (357). Scanning electron microscopy (SEM) utilises an electron beam that is scattered across the surface of the sample to produce a magnified image of an object (365). SEM is now not usually used for imaging lipid vesicles because it requires the sample to be fixed or air-dried prior to imaging, which can cause damage to the particle's integrity due to the surface tension of the evaporating water (364,366). However, special drying techniques, such as the critical point drying, or paper absorption, followed by ethanol concentration gradients, have been successfully used to prepare the sample before SEM analysis (364,367). Also, freeze-dried powders of lipid vesicles can be analysed using this technique to study the morphology of the vesicles (365,368).

Environmental scanning electron microscopy (ESEM) is an improved imaging system that does not require the use of fixing, staining or freezing of vesicles to visualise wet systems (369). ESEM allows the presence of vapour in the sample chamber, since a multiple-aperture vacuum system lets the imaging chamber be maintained in a partial vacuum environment, unlike other parts of the equipment (370).

Transmission electron microscopy (TEM) is probably the most frequently used imaging technique for lipid vesicle imaging (281,371). It provides a better contrast and contour of vesicle structures than other microscopy techniques, thus it easily denotes information about structure and surface modifications of vesicles (357). In contrast to scanning-based microscopy, the electron beams cross the samples and are refocused by different lenses to form an image. It requires sample-preparation procedures prior to visualisation, specifically negative staining, freeze-fracture and cryo-TEM (372–374). The negative staining is a fast

preparation technique and allows the use of hydrated samples. It consists of embedding the vesicles in electron-dense materials, typically heavy metal salts like phosphotungstic acid or uranyl acetate, which enhances the contrast between them and the background (375). The most relevant inconvenience is the difficulty in evaluating the vesicle morphology. The possibility to introduce artefacts that may be mistaken for vesicle structure and entities (376), and the changes in the structure of vesicles as a consequence of vacuum atmosphere and dehydration of the samples are other important limitations (370). The freeze–fracture technique involves vitrification by quick freezing using cold liquids such as propane or nitrogen (377). Then, samples are fractured and surfaces etched to get a negative replica of the fracture sample (378). The main advantages of freeze-fracture TEM are that it can provide information about the internal structure and does not require any drying pre-treatment. However, it requires the use of organic solvents to clean the replicas of the samples that are removed prior to visualisation (357). Cryo-TEM is the most evolved technique of microscopy currently available (379,380). The native state of lipid vesicles can be evaluated through it, receiving complete information about size, shape, internal structure, and lamellarity (381,382). The aqueous films are vitrified in liquids such as ethane, and the quick freezing of samples prevents the crystallisation of drugs and vesicle components and minimises the appearance of artefacts (357).

As a variation of the scanning microscopy technique, atomic force microscopy (AFM) is an interesting alternative to visualise nanoparticles and analyse their surface modifications and ligands detection, thanks to its high resolution in the order of fractions of a nanometer (383–386). AFM consists of a sharp tip attached to a cantilever and connected to an optical sensor with a laser beam that records and quantifies the cantilever deflection (387). The system explores the sample surface and it moves up and down the cantilever as a result of the surface relief. The main advantage of AFM is that it can operate in a liquid or air environment, and it does not need a vacuum condition (357). On the other hand, the main

limitations are the need to adsorb the nanoparticles onto mica or silicon surfaces, which can potentially modify the size and shape of the lipid vesicles (388), and their displacement and dragging as result of their contact with the tip and cantilever (357).

3.1.6.4. Polydispersity index

As mentioned before, vesicle size has an important impact on transdermal permeability as well as on therapeutic efficacy. Successful formulations should be efficient, stable and safe, which demands homogeneous populations in the case of pharmaceutical nanoparticles (389–391). PDI is the parameter that evaluates the size distribution of a population of particles (392,393). As for size, PDI is accurately determined using DLS. It is scaled to the unit, so that its values are ranged from 0 to 1. In general, values lower than 0.5 refer to monodisperse systems, whereas results above 0.7 indicate high polydisperse populations. In drug delivery, PDI values of 0.3 and below are considered acceptable for lipid-based carriers, and indicate homogeneous populations of phospholipid vesicles (349). Size reduction methods like sonication, extrusion, and high-pressure homogenization have been reported to reduce excessive PDI values (394–397).

3.1.6.5. Vesicle flexibility

The degree of deformability is the differential feature of flexible lipid vesicles in comparison to common liposomes. It seems to be the key aspect that allows the improvement in drug permeation and permeability by transfersomes and ethosomes (398). The flexibility of a lipid vesicle depends on the composition and the incorporation of the edge-activators. Different simple methods have been proposed for the determination of this degree of deformability to compare the flexibility of different vesicle batches. Essentially, two techniques based on the extrusion procedure are used. The first one consists of the measurement of the vesicle suspension volume recovered after extrusion, which is directly proportional to the flexibility. Thus, the more deformable the vesicles are, the more freely they will pass

through extrusion membranes without saturating the extrusion membrane and leading to a minimum volume loss (79,281,399). The alternative method compares the size before and after the extrusion process. The reduction in size is inversely proportional to the flexibility, as the more flexible vesicles can squeeze through the membrane pores maintaining their size (400,401). A deformability index has been proposed using the following equation (equation 3.1) (402):

Equation 3.1:

$$D = J \cdot \left(\frac{rv}{rp}\right)^2$$

Where J is the volume of formulation extruded; rv is the particle size after the experiment; rp is the membrane pore size.

3.1.6.6. Drug release

The design and optimisation processes of lipid vesicles imply the analysis of drug release mechanisms that constitutes the first and indispensable step after *in vivo* administration. The *in vitro* methods to study drug release are similar to the purification ones, such as the centrifugation/filtration and dialysis method, but applied under completely different experimental conditions (403). Dialysis methods are commonly used since they are simple and cost-effective (227). The solubility requirements of drugs in the acceptor medium and the maintenance of sink conditions are the main limitations (404). Even though drugs released from vesicles must cross an extra barrier (the dialysis membrane), it does not interfere if first and zero order kinetics are representative of the process, and the release rate from vesicles is higher than or equal to the diffusion rate through the dialysis membrane. Thus, the limiting step here is the release process. The experimentally obtained data reflects the release behaviour in all cases (79,227). The dialysis methods are usually carried out using FDC set-ups or dialysis tubes systems in a physiologically tempered environment at 32-37°C (405,406).

Rigidity and structure of vesicles can modify the release patterns of drugs. MLV present a higher number of barriers that drugs should overcome, which increases drug retention inside the structures and delays the diffusion process through the membranes (321). Vesicle composition modulates the rigidity because cholesterol acts as a membrane stabiliser, diminishing the fluidity of phospholipids and increasing the rigidity. In fact, it has been reported that rigidity increases the resistance to drug transport and therefore diminishes drug release (229,407). On the other hand, the hydrophilic or lipophilic character of molecules is the other main factor that influences drug release, as hydrophilic drugs present higher and faster release processes in aqueous media in comparison to lipophilic substances (227,408).

Release data is often fitted to different kinetic models that propose the underlying release mechanisms and allow quantitative release rate comparisons. Theoretical models such as zero and first order kinetics have been used, but empirical models generally offer more complete information (409). Higuchi, Korsmeyer-Peppas, and Peppas-Sahlin are the semi-empirical mathematical models usually applied to the drug release from vesicular systems. Among them, the Higuchi model seems to be the most limited as it assumes that the process is carried out exclusively by passive diffusion (410). The Korsmeyer-Peppas and Peppas-Sahlin models consider both a relaxation mechanism and passive diffusion with different impact in the whole release process (411–413). A modification of the Korsmeyer-Peppas model, also called the Power-law model, was introduced by Kim and it considers a possible burst effect during the initial moments of drug release (414). However, burst effects can be attributed to free drugs present in the media when vesicles are not adequately purified or if the drug has been released from the TDS during the storage.

The suitability and accuracy of the different fitting models to the experimental data is commonly evaluated by the correlation coefficient (R^2) and the Akaike information criterion (AIC) (equation 3.2) (415–417). The

AIC is very useful to compare models with a different number of parameters, since it compensates for the statistical versatility of equations with lower degrees of freedom using a penalising factor. The correlation coefficient is usually reported as an indicator of the proportion of the results variability that is explained by the model.

Equation 3.2:

$$AIC = n \cdot \ln(SSr) + 2 \cdot p$$

Where n is the number of experimental data; SSr is the residual sum of squared; and p is the number of parameters in the mathematical model considered.

3.1.6.7. Stability

The stability of lipid-vesicles formulations is a key issue in drug delivery, as it determines the feasibility of any pharmaceutical product to be commercially available (418). Stability-related phenomena can be classified into two groups: immediate or long-term changes. In general, zeta-potential works as a good predictive stability parameter of colloidal particles such as lipid vesicles (419). High values above ± 30 mV assure a great repulsion between the surface charged particles, which produces an electrical stabilisation of the particles and leads to a low aggregation or flocculation (420). Temperature clearly affects the stability of vesicles, for which they are stored at 4°C until their use (421). However, they still present some stability issues, which are in fact one of the main limitations of lipid-vesicles (221).

3.1.6.7.1. Immediate or short-term stability

Physical stability refers to phenomena occurring in the days or weeks following lipid-vesicles production. Creaming-clarification, aggregation, coalescence, sedimentation, and flocculation are typical events of instability that vesicles can show relatively often (Figure 3.3). These phenomena are easily detected by size and PDI measurements carried out with DLS (Table

3.3) (422). Additionally, Turbiscan® is a complementary tool to check the phenomena that vesicles experience during the early storage period. It records the variation of transmitted and backscattered light by the sample over the time (Table 3.3). In addition, it offers the Turbiscan Stability Index (TSI), which expresses a global idea about the stability of the formulation.

Table 3.3. Possible changes of lipid vesicles observed in a short-term period by DLS and Turbiscan®. Δ BS: variation of backscattering. Δ T: variation of transmittance.

	Vial Bottom		Vial Middle		Vial Top		Size	PDI
	Δ BS	Δ T	Δ BS	Δ T	Δ BS	Δ T		
Sedimentation	↑	↓	-	-	↓	↑	↑	↑
Creaming	↓	↑	-	-	↑	↓	↑	↑
Flocculation	-	-	↑/↓	↑/↓	-	-	↑	↑
Coalescence	-	-	↑/↓	↑/↓	-	-	↑	↑

Coalescence and flocculation lead to an increase in particle size. Coalescence is irreversible as it entails the fusion of vesicles, while flocculation is an aggregation of particles without the creation of single drops (423,424). Flocculates are often easily dispersible, unless they coagulate. Moreover, flocculation can lead to coalescence at some point. Creaming is rarely observed in lipid-vesicle storage. It takes place when the dispersed phase has lower density than the continuous phase and goes up to the top of the vial sample. Creaming can be coupled with coalescence, flocculation and even phase separation. On the other hand, sedimentation is a similar process. The density of the dispersed phase is higher than the density of the continuous phase, and the fraction of particles migrate to the bottom of the vial sample (425). Clarification is an associated phenomenon that implies particle depletion of a part of the sample.

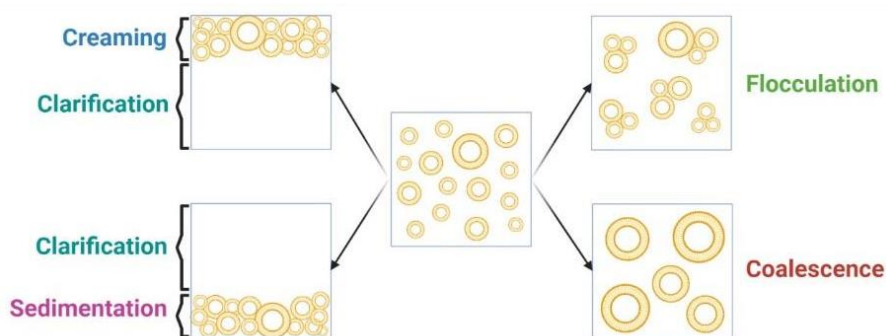

Figure 3.3. Short-term instability phenomena that lipid-vesicles can show during the storage period: flocculation, coalescence, clarification, creaming and sedimentation.

3.1.6.7.2. Long-term stability

It has been reported that lipid-vesicles may be stable for 2-3 months (426,427). During this period, the phenomena described above can continue. Additionally, if vesicles suffer the destabilisation of lipid bilayers or changes in storage conditions, they can disintegrate. Nevertheless, the main issue during the long-term storage is drug leakage, which takes place especially in vesicles loaded with hydrophilic drugs, as a consequence of their affinity for the media where the vesicles are dispersed (428). Rigid vesicles, with high amounts of cholesterol, can control drug leakage, but will slow down in drug release.

3.1.6.7.3. Freeze-drying

Freeze-drying or lyophilisation is the easiest method to preserve lipid vesicles during long periods of storage. It removes the aqueous content of the formulation and therefore avoids chemical reactions, such as oxidation, which can affect the vesicle structure (429,430). Moreover, drug leakage is prevented since there is not a media to which to diffuse.

Freeze-drying is a complex process that has three main steps: freezing, sublimation, and secondary drying. There is not a general recipe

that works with all formulations, and each one requires the development of a specific protocol of temperature, pressure, and time according to its own characteristics. It is particularly important to attain the whole sample freezing prior to the vacuum phase to get an optimal result. Therefore, it is essential to determine the critical collapse temperature for the preparation, which is the maximum temperature that can be used during drying (431). As amorphous structures, lipid vesicles substances have a glass transition temperature instead of an eutectic point (432), and the collapsing temperature is usually a few degrees higher (433,434). The use of organic solvents is also a problem, as lower temperatures are required to freeze, and they can easily bypass the condenser during the following phases and damage the equipment. On this matter it seems impossible to proceed to ethosomes lyophilisation, as ethanol is also removed from the formulation as a consequence of its high volatility and vesicles would be reconstituted in water (435). The next step dries the sample by removing the bulk of the water via sublimation, and it is divided into two steps (Figure 3.4).

Figure 3.4. Standard phase diagram of water. The process starts with the freezing of the formulation, and the drying steps take place by dropping down the pressure level and increasing the temperature.

Primary drying is a slow phase, conducted at cooler temperatures than the critical collapse temperature of the freeze-dried formulation. The

product temperature depends on its vapour pressure, which in turn, is determined by the heat transfer to the product (controlled by the shelf temperature) and the vacuum level. Provided the optimal temperature of the formulation is identified, the parameters to control during the primary drying are the shelf temperature and the vacuum level (436). The amounts of residual water still bound to the formulation after this process is desorbed in the secondary drying by increasing the temperature (437,438). This increase must be controlled and slowed to avoid the collapse of the formulation.

Depending on the further applications of the formulations, the final water content varies from 0.5 to 3%, but in most cases, the driest products will have a longer shelf life. Thermogravimetric analysis (TGA) can be used to set up the freeze-drying conditions and as a control of the final product, since it measures the mass loss and its rate as a function of temperature. In thermograms, different steps of mass loss can be detected and the first one is used to correspond with the moisture content of the sample (Figure 3.5) (439,440).

Figure 3.5. Standard profile of a thermogravimetric analysis. The first phase of weight loss corresponds to the water content which must range between 1-3% for freeze dried products.

Lyophilisation of lipid vesicles can be achieved with just the primary drying step (441,442). Vesicles must be previously frozen around -80°C for at least 6-12 h to assure a complete freezing of the sample. For the primary drying (24-48 h), shelf temperature must be set around -40°C, condenser temperature -55/-60°C, and pressure 1-6 Pa. In the case of a multiple step drying, a constant rate of 0.25°C/min or additional cycles of 5 h with a decreasing shelf temperature are used, for instance -30°C, -16°C and 20°C (443). The final products can be stored during long periods at 4°C prior to use. An optimal lyophilisate should be a cake composed of a uniform, fine and smooth powder, easily hydratable and dispersible in water.

Different phenomena can lead to changes in the lyophilised cake appearance with critical, major, or minor consequences in the product efficacy and safety. The most common are collapse, melt-back, and puffing. Collapse is usually a consequence of a drying (primary or secondary) above the collapse temperature of liposomal formulation and results in a viscous flow and loss of the microstructure previously established by the freeze process (444). Melt-back takes place due to traces of ice remaining at the end of primary drying or in the early moments of secondary drying (445,446). Consequently, it happens if primary drying occurs above the eutectic point or if primary drying is incomplete. Both are undesirable in all cases since they have an important impact on the final product quality and attributes. Puffing consists of the presence of bubbles on the top surface of the dried product. Different reasons can cause its appearance, such as minimum collapse or small melting during drying. During the freezing process small bubbles of air are included, which can migrate to the surface and, if they are stable enough to withstand the drying, remain in the final product (444,447). Contrary to collapse and melt-back, puffing does not imply in all cases critical consequences in the quality of the final product and is acceptable when it is observed as a characteristic of the formulation in all vials within a batch without any impact on the product attributes. In case of observing it in a few vials of a batch, the product showing puffing evidence should be discarded (444).

The use of cryoprotective agents is generally recommended to preserve the starting characteristics and vesicle integrity. Amino acids and complex polysaccharides have been used as cryoprotecting agents (448,449); however, simple saccharides are generally considered the first-choice excipients. Their mechanism of action is not completely understood, and different theories have been proposed which are not exclusive and may work together. On one hand, the water replacement theory suggests that the H-bonds interactions between water and polar head groups of phospholipids are replaced by those with the carbohydrates, stabilising the vesicle structure (450). On the other hand, the vitrification model proposes that sugars produce a phase with high viscosity and low mobility, which allows to maintain the distance among vesicles acting as a barrier between adjacent bilayers. This matrix protects the bilayers from damages caused by ice formation and prevents the fusion of vesicles. In consequence, sugar avoids the increase of T_m and the possible leakage of hydrophilic drugs induced by the effect of extra-vesicular ice (451). For example, glucose, lactose, sucrose, mannitol and maltose have been used in a 5-10:1 molar ratio (cryoprotectant: lipid) (Table 3.4) (452). Sorbitol has been prepared at 0.7-2.5% (v/v) solutions and then mixed in a 1:4 ratio (vesicle sample: cryoprotective solution) (281). After the reconstitution of freeze-dried vesicles, parameters such as size and PDI are maintained in most cases. Nevertheless, some reports show that the use of sugars can produce a tiny but significant size decrease after lyophilisation, which is higher when sugar concentrations are increased (441,453). As an explanation of this, several reasons have been accounted for, but the loss of water content in the membrane for preventing vesicle damage as a consequence of kosmotropic effects seems to be the most reliable cause (454).

Table 3.4. Glass transition temperature (T_g) of some common cryoprotecting sugars. Taken and modified from Levine and Slade, 1988 (455).

Cryoprotectant	T_g (°C)
Glucose	-43
Lactose	-28
Sucrose	-32
Mannitol	-40
Maltose	-29.5

3.1.6.7.4. Differential scanning calorimetry

DSC has been widely used to characterise solid components and stability (456). The technique supplies heat at a constant rate to a sample and a reference material -usually between 1-20°C/min from 25 to 300°C range- (457–460), with the aim of comparing and determining the difference in the heat flow needed to keep both at the same temperature (461). Thermal analysis represents the heat flow difference between the samples and the reference material, which is plotted versus temperature (Figure 3.6). It allows the identification and determination of different material state transitions like glass transition temperature (T_g), degradation temperature (T_d), melting temperature (T_m) or crystallisation temperature (T_c). First-order transitions, such as crystallisation, melting and degradation, imply an abrupt absorption or release of latent heat and are depicted as well-defined peaks in thermograms (462). Second-order transitions, like glass transitions, do not involve a change in volume or latent heat, since they are just associated with variations in molecular mobility (463). Consequently, it is observed as a slight change in the slope that may take place in a large range of temperatures. These parameters and phase transitions are essential for a complete understanding of the relationship between the properties and the structure of materials. As a result, DSC provides a characterisation of the solid materials or powders (including lyophilised lipid vesicles), providing key information about the interaction of their constituent components and its evolution over the time.

Figure 3.6. Standard DSC analysis profile. Glass transition temperature (T_g) is observed as a slight change in the slope that can take place in a wide range of temperatures. Crystallisation (T_c), melting (T_m), and degradation (T_d) temperatures are observed as well-defined peaks.

The main limitations of DSC are, on one hand, the analysis of multicomponent samples that generate thermograms with complex signals, which can be different from those provided by pure constituents that make the correct identification of transitions and thermodynamic changes difficult. On the other hand, the overlapping thermogram profiles are also dependent first, on the heat rates used and second, on the fact that melting and degradation can occur in a narrow range of temperatures (461).

3.1.6.8. Biocompatibility

Lipid nanocarriers are composed predominantly by phospholipids, which are considered by regulatory agencies as safe components (464). However, the chemical modifications in its structure and the inclusion of other additional components may potentially lead to an increase of the toxicity of the resulting liposomes. Even though lipid vesicles increase the therapeutic index of many drugs by decreasing drug accumulation in other organs and healthy tissues, they can produce toxic effects in the target tissues or elicit immune responses (465). In particular, the interaction with proteins and vesicular systems can trigger the innate immune responses

such as the activation of complement cascade, cytokine production, and hypersensitivity reactions. In the same way as the other aspects related to lipid vesicles, the final biocompatibility or toxicity is the result of the combination of different properties and features such as size, surface charge, and composition (465,466). Thereby, *in vitro* and *in vivo* evaluation of lipid vesicle biocompatibility has become a compulsory step in their design and development.

In vitro toxicity is assessed as viability tests on cell lines such as diploid fibroblast strain MLD and 3T3 mouse fibroblast (467,468), NEB-1, SCC, HaCaT and HEK as representative of keratinocyte lines (469–471), B16F10 murine melanoma cells (472), and RAW 264.7 murine macrophages (473,474). These assays include 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) or lactate dehydrogenase (LDH) tests (475–477). Cell viability results are generally expressed as percentage of viability, and those above 80% are considered non-toxic, between 80-40% as weak-moderate and below 40% as cytotoxic (478). The main limitation of these protocols is the possible *per se* interference of lipid vesicles as a consequence of their lipidic nature, since certain vesicle components can induce and stimulate cell growth (479).

For the *in vivo* evaluation of side effects, the Buehler test has been used extensively. It is considered a conservative test with relevance to the clinical condition (480). In the Buehler sensitisation test, a single occlusive patch containing a minimally irritating concentration of the tested formulation is applied to the shaved flanks of guinea pigs for 6 h. This procedure is repeated 2 times more on the same site once a week. After a 2-week rest period, the animals are challenged with an occlusive patch with the highest non-irritating concentration of the test material at a naive skin site. The patch challenge test sites are evaluated 24 h and 48 h after removal for the presence of erythema using a scale of 0-3, in which 3 represents intense erythema. Additional control groups of animals are

needed and similarly challenged. The incidence of severity of responses in the test group is calculated relative to that in the control group.

If the point of application is the eye, the Draize test was the most used assay to assess the irritating properties of the formulation (481,482). However, there are many ethical concerns related to animal testing and the scientific community is searching for alternative methods. This test is based on the blinking produced by 0.1 mL of the studied formulation in the rabbit eye compared to a saline-treated control eye. Irritation levels are registered at 24, 48, 72 h and 4, 7, 14 and 21 days following application using a score from 0 (non-irritative) to 100 (maximally irritative) (483). As an *in vitro* alternative for testing ocular irritation, the Bovine corneal opacity and permeability (BCOP) test has been proposed. After *in vitro* experiments where cornea or sclera are used, ocular tissues are visually inspected looking for any damage or appearance modification that indicates irritation (484–486). However, in many cases this test is not considered strong enough to assess the complete safety of formulations and other tests are needed. Hen's Egg Test Chorioallantoic Membrane (HET-CAM test) is probably one of the most accepted alternatives to the Draize test (487,488). In order to conduct it, fertilised eggs are placed and maintained for 8 days in the incubator at $37 \pm 0.5^{\circ}\text{C}$ with $40 \pm 5\%$ environmental humidity. They are turned 3-5 times per day to prevent the attachment of the embryo to one side of the egg. At the end of the 8th day, eggs are placed with the large end facing up for 24 h to ensure the moving of the embryo to the bottom of the egg. On day 9, eggshells are cut in the air chamber area without damaging the membrane, which is moistened for 30 min with 2 mL of 0.9% NaCl solution before removing it to expose the chorioallantoic membrane (CAM). Around 200 μL are deposited in the CAM and eggs are observed for bleeding, vascular lysis, and coagulation of the CAM vessels for 300 sec (489). The irritation score (IS) is calculated according to the following equation (equation 3.3) (490):

Equation 3.3:

$$IS = \frac{(301 - tH) \cdot 5}{300} + \frac{(301 - tL) \cdot 7}{300} + \frac{(301 - tC) \cdot 9}{300}$$

Where tH is the haemorrhage time (s), tL is the lysis time (s) and tC is the coagulation time (s). Substances are classified as no irritation ($IS < 1$), weak irritation ($1 \leq IS < 5$), moderate irritation ($5 \leq IS < 9$), and severe irritation ($9 \leq IS < 21$) (483).

Luckily, topical application of lipid vesicles does not entail frequent side effects in *in vitro* studies, since cells are often insensitive to the toxic effects of vesicles showing higher compatibility than the corresponding drug solutions, and well tolerated in *in vivo* models when they are given topically (491). On this matter, the administration of liposomes containing a high proportion of negatively charged phospholipids has been related to the drying effect on the skin, and stearylamine to irritation if applied topically in the eye (480).

3.2. Microneedle arrays

Microneedle arrays (MNA) are devices that contain microscopic needle-like projections that can perforate the *stratum corneum*, creating ducts that facilitate the flow of large molecules (> 500 Da), proteins and nanoparticles through the skin (492). Different types of MNA have been designed, including solid, coated, hollow, dissolving, and hydrogel-forming microneedles. The microneedle field has been growing constantly since the registration of the first patent (solid and hollow microneedles) by Gastrel and Place in 1971, and shortly after, the second one (coated microneedles) by Paul in 1975. However, we had to wait until the year 2000 for the emergence of dissolving microneedles and the current main applications of MNA, which include gene delivery, vaccination, diagnosis, and cosmetic applications (493). MNA are a clearly emerging field within pharmaceutical research, given the rising number of articles being published since the appearance of the “microneedle” concept. In particular, the number of microneedle advertisements was moderate and steady before the year

2000, but since then, there has been a progressive increase year after year. An autoregressive integrated moving average model (ARIMA) study that extrapolates future trends in the short-medium term based on previous data, identified and predicted a growing trend that is currently being met (494). The number of patents registered in recent years also shows a continuous growth of MNA as drug delivery systems (495–497). The interest in MNA is related to advantages such as ease of use (can be self-administered and removed) and controlled release of drugs. Moreover, they can be considered a painless transdermal delivery system because the size of microneedles is enough to surpass the first layers of the skin, while avoiding contact with nervous terminations present in the dermis (498).

3.2.1. Microneedle-based transdermal delivery approaches

The success of MNA-based drug delivery is determined by critical issues, mainly concerning the design of the MNA (shape, size, geometry, and manufacturing materials and processes) and the type of active substance delivered. The different strategies can be classified as: “*poke and patch*”, “*poke and flow*”, “*coat and poke*”, and “*poke and release*” (499).

3.2.1.1. Solid MNA for “poke and patch”

The “*poke and patch*” approach consists of the use of solid MNA to perforate the skin, creating microchannels that reach the deepest layers of the epidermis. This method significantly improves the passive transport of drugs through the skin, since the main barrier to permeability, the *stratum corneum*, is disrupted (500,501). This approach presents two steps: first, the MNA are used to pierce the epidermis and are subsequently removed; and second, the drug is applied in a conventional dosage form (solution, cream, or patch), which works as an external drug reservoir (Figure 3.7) (502). Its simplicity, from a technological point of view, makes it highly attractive, especially for its easy application in a clinical setting. However, this technique is not exempt from controversy and presents several disadvantages. One of the main drawbacks is that the micro-pores remain open only for a limited time, potentially stopping the delivery of the active

substance prematurely. It has been reported that all microneedle-treated sites recover their barrier properties within 2 h (501). Nevertheless, this period can be extended up to three days under occlusive conditions by using formulations like patches or tapes (503), although the risk of infection increases considerably in these conditions (504).

Figure 3.7. Schematic representation of “poke and patch” approach.

3.2.1.2. Coated MNA for “coat and poke”

Another approach with solid MNA is the “coat and poke” technique which requires the coating of the solid microneedles’ surface with a drug or vaccine-loaded formulation (505). This strategy allows drug diffusion from the coating surface to the deeper epidermal layers after MNA insertion (Figure 3.8) (506). Certain issues, mainly related to the coating, limit the usefulness of this approach. For instance, the amount of drug which can be encapsulated in the coating layer is relatively low. Furthermore, the coating’s thickness can decrease the sharpness of the microneedles and influence their ability to perforate the skin (507). Despite this, coated MNA have shown great efficiency in vaccination, since the antigen dose needed to trigger an immune response is usually in the range of nano or micrograms (508).

Figure 3.8. Schematic representation of “coat and poke” approach.

3.2.1.3. Dissolving and hydrogel-forming MNA for “poke and release”

Dissolving MNA can be made from a range of water-soluble and biodegradable materials in which drugs can be loaded and released as the MNA dissolves after insertion (Figure 3.9) (509,510). The improvement seen in this approach in comparison with the “*poke and patch*” is that dissolving microneedles can maintain controlled drug release over a longer period of time, by controlling the dissolution rate of the formulation used as the MNA matrix. Another advantage is that it reduces the drug administration process to one step, as the MNA are able to pierce the skin and are kept inserted until complete dissolution (511,512). Moreover, dissolving MNA avoid the generation of sharps waste, minimising the cost related to its management and reducing needle-stick injuries. On the other hand, drawbacks include a limited drug loading and a potentially lower ability to perforate the *stratum corneum*.

Figure 3.9. Schematic representation of “poke and release” approach.

Rapidly separating MNA were designed as a hybrid between coated and dissolving MNA (Figure 3.10) (513). The aim is to insert into the skin a drug-loaded water-soluble matrix encapsulating the drug, coupled with a

solid MNA composed of an insoluble polymer. This second array helps the insertion of the soft matrix that remains in the skin, while the solid MNA can be easily removed afterwards (514,515). As an evolution of these MNA, more sophisticated designs have been developed. The insertion of air bubbles in the MNA structure, between the tips and the patch base, enables the easy and rapid separation of the microneedle's tips from the backing structure after insertion, leaving the tips in the skin and generating non-sharps waste (516).

Figure 3.10. Schematic representation of rapidly separating MNA.

As an alternative to “poke and patch” approaches, hydrogel-forming MNA or swellable MNA have been developed (Figure 3.11). The aim of these devices is to imbibe skin interstitial fluid upon insertion to form continuous, unblockable microchannels amongst dermal capillaries. This approach allows the release of less potent drugs contained in an attached patch-type drug reservoir (517,518).

Figure 3.11. Schematic representation of hydrogel-forming or swelling MNA.

3.2.1.4. Hollow MNA for “poke and flow”

The “*poke and flow*” approach was conceived to introduce a drug solution into the skin mimicking hypodermic injections while overcoming their limitations (519,520). In this approach, the microneedles play a similar role to hypodermic needles, through which drug formulations are administered after skin perforation (Figure 3.12). Due to their micrometric size, their manufacturing process is difficult and expensive, requiring significant technological resources. By contrast, thanks to the shorter size of these needles, the average patient’s acceptance of this approach is higher than that of traditional injections.

Figure 3.12. Schematic representation of “poke and flow” approach.

3.2.2. MNA fabrication: materials and manufacturing processes

MNA are produced using a wide range of materials. All of them must show key properties for the final success of this technology. Any material used for manufacturing MNA should present certain characteristics: inert nature, absence of immunogenicity, high tensile strength, mechanical strength, low corrosion rate, biocompatibility, and stability. The most common materials for making MNA are metals, silicones, ceramics, glass, sugars, and polymers (Table 3.5).

Table 3.5. Summary of materials and methods used to manufacture MNA.

Material	MNA Type	Fabrication Process	Ref.
Stainless steel, Titanium, Nickel, Gold	Solid, Hollow coated	Laser cutting, laser ablation, etching, electropolishing, lithography.	(521–527)
Alumina, Zirconia	Ceramic	Lithography and ceramic sintering	(528–531)
Silicon	Solid, Hollow coated	Etching, lithography	(532–535)
Borosilicates	Hollow	Pulling pipettes	(519,536–538)
Sugars	Solid, Dissolving	Solvent casting or micromoulding	(539–542)
Polymers	Dissolving, Hydrogel-forming, Coated	Solvent casting or micromoulding	(513,543–552)

The material or main component of MNA determines the most appropriate microneedle manufacturing technique. The main advantages and disadvantages are summarised in Table 3.6. In any case, the selected method should be precise, accurate, reproducible, and robust. The most commonly used techniques include laser cutting, laser ablation, electrodeposition, lithography, etching (Table 3.5) (553). However, micromoulding (also known as solvent casting) is the main trend in basic research, which consists of the use of 3D-printed structures to produce negative moulds that are filled with polymeric solutions. After solvent removal, a polymeric MNA with an identical shape and size of the 3D-printed model is obtained (554).

Table 3.6. Summary of advantages and disadvantages of MNA.

MNA Type	Advantages	Disadvantages	Ref.
Stainless steel, Titanium, Nickel, Gold	Desirable mechanical properties and high tensile strength	Fractures, corrosion, and poor compatibility of some metals	(521–527)
Alumina, Zirconia	Good biocompatibility	Fractures	(528–531)
Silicon	Desirable mechanical properties	High material cost, long fabrication, and fractures	(532–535)
Borosilicates	Good biocompatibility	Fractures	(519,536–538)
Sugars	Good biocompatibility	Mechanical properties are difficult to achieve, stability problems, storage issues	(539–542)
Polymers	Good biocompatibility, biodegradation, and absence of waste after use	Mechanical properties are more difficult to achieve	(513,543–552)

3.2.3. Safety considerations

As with any pharmaceutical formulations, MNA must be rendered safe in order to be accepted as a true alternative to classical drug delivery technologies. Three basic undesired effects could happen after the insertion of MNA: pain, infections, and local skin reactions (inflammation, erythema, irritation, etc.).

3.2.3.1. Pain

Patient's compliance and acceptance depend mainly on the pain generated by MNA in comparison with conventional injections. MNA should produce significantly less pain than a hypodermic needle, since the needle tips in MNA do not usually reach the dermis, where nerve endings are located. Several studies have demonstrated that pain depends on the length and number of needles in the MNA. Gill et al. (2007) observed that

MNA are less painful than a 26-gauge hypodermic needle and established a correlation between the pain level and the number and length of the microneedles (555,556). Particularly, the authors tested needles with lengths of 480, 700, 960, and 1450 μm , finding that the pain levels they produced varied between 5-37% of those obtained with the hypodermic needle. Additionally, a 10-fold increase in the number of projections produced a relatively small increase in pain, from 5 to 25% in comparison with a hypodermic-needle. Bal et al. (2008) tested the pain generated by microneedles below 550 μm in length, finding very low pain scores in all cases with no significant differences between them (557). However, pain and skin reactions can be produced by the breakage of the microneedles during insertion, which may be possible, and is especially associated with certain materials, such as glass and ceramics (538).

3.2.3.2. Infections

Open channels created by MNA can potentially become a gateway for the entry of microorganisms into the body. The development of infectious processes is directly related to disruption of the skin's barrier function. In turn, the time that the micro-pores remain open depends largely on some characteristics of the MNA, such as the length of the tips. This relationship has already been stated; for example, Kalluri et al. (2011) studied the *in vivo* kinetics of pore closure using calcein imaging, and observed that this process lasts about 15 h when exposed to the environment and up to 72 h under occlusive conditions (503). This period is similar to the estimated one for a hypodermic needle channel. The barrier function of the skin was also evaluated using the TEWL levels, indicating that the skin only needs 4 h to recover its barrier function after treatment with 550 μm long microneedles. Bal et al. (2008) reported a trend that using longer microneedles resulted in a higher increase in TEWL values, since a significant difference in response was observed between needles with lengths of 400 and 200 μm (557). Furthermore, the study of Donnelly et al. (2013) showed that microneedle puncture resulted in significantly less microbial penetration than hypodermic needle puncture and that no microorganisms crossed the

viable epidermis in microneedle-punctured skin, in contrast to needle-punctured skin. Therefore, it could be stated that the correct application of MNA to skin would not cause either local or systemic infection in normal circumstances in immune-competent patients (558). Particularly, excised porcine skin, Silescol[®] membranes and radiolabelled microorganisms were used in the experiments, which showed that the number of microorganisms that crossed the membranes were an order of magnitude lower when the membranes were punctured by microneedles rather than with a 21 G hypodermic needle; and the number of microorganisms penetrating the skin beyond the *stratum corneum* was approximately an order of magnitude greater than the numbers crossing Silescol[®] membranes in the corresponding experiment.

3.2.3.3. Biocompatibility, immunogenicity, and local skin reactions

The presence of strange objects or biological incompatibility of any component could trigger skin inflammation, irritation, or erythema during or after treatment with MNA. Bal et al. (2008) checked the possible impact of microneedle length on irritation, examining the redness of the skin, and blood flow (557). Both methods measure erythema, one of the fundamental indicators of inflammation. Changes in redness were observed after the application of solid metallic MNA, reaching maximum irritation values after 15 min and returning to the basal values in approximately 90 min. For those MNA, an increase in length (200, 300, and 400 μm) results in an increase in redness, although only the differences between the smaller length and the rest were statistically significant. Moreover, the treatment with MNA of various lengths did not result in significant differences in blood flow. On the other hand, Vicente–Pérez et al. (2017) did not find any significant evidence of an increase in sera biomarkers of inflammation and irritation (TNF- α and IL-1 β) after a prolonged use of polymeric MNA (559).

Low biocompatibility or allergic responses are not frequent in microneedle-based approaches, especially with polymeric MNA since the manufacturing materials are commonly transferred from other fields of

pharmaceutical technology where compatibility has been guaranteed. However, other types of MNA, such as the solid and hollow ones, might be associated with some issues. For example, stainless steel MNA can suffer corrosion over time, a feature that has been clearly improved by using titanium (560). In addition, nickel MNA have been designed and used despite the fact that nickel has shown cytotoxicity and intracellular accumulation in human HaCat keratinocytes (561–563).

Some studies have demonstrated that MNA do not stimulate the humoral immune system, as shown in the work of Vicente–Pérez et al. (2017) (559). Here, they used three well known sera biomarkers such as C-reactive protein, TNF- α , and IgG to monitor possible infection and inflammatory processes associated with two dissolving MNA treatment regimens, using an *in vivo* model. TNF- α levels were undetectable in all mice, and no statistical differences were found for the other measured biomarkers, regardless of formulation type, needle density, number of applications, or mouse gender.

Chapter 4

Development and validation of an analytical method for cyanocobalamin

4.1. Materials and methods

Cyanocobalamin (B12) was quantified in all experiments by HPLC with Ultraviolet detection or UV-Vis spectroscopy. The analytical method developed is based on that previously described by Li et al. (2000), including certain modifications to adapt it to the equipment used (564).

4.1.1. Materials

The reagents used are listed in table 4.1.

Table 4.1. Reagents for validating the analytical method.

Reagent	Quality	Supplier
Water	HPLC-grade	Milipore (Madrid, Spain)
Methanol	HPLC-grade	VWR (Radnor, PA, USA)
Cyanocobalamin	> 95% purity	Acofarma (Madrid, Spain)

4.1.2. Equipment

A PerkinElmer Series 200[®] HPLC (PerkinElmer; Waltham, MA, USA) equipped with an automatic injector and UV-vis detector was used. TotalChrom Workstation[®] software was employed to process the chromatograms and determine the area of the peaks.

4.1.3. Stationary phase and mobile phase

The mobile phase consisted of an isocratic mixture of methanol:water (30:70). The stationary phase was a Kromasil[®] C18 HPLC column of 5 μ m particle size, pore size 100 Å, L x I.D. 150 mm x 4.6 mm (Dr. Maisch GmbH; Ammerbuch, Germany).

4.1.4. Analytical conditions

The injection volume was 50 μ L, and the detector was settled at 360 nm. The mobile phase was delivered at a flow rate of 0.7 mL/min, and the analysis of the samples was carried out at room temperature.

4.1.5. Validation of the analytical method

The method was validated regarding linearity, sensitivity, precision, and accuracy. To this end, the area of the peaks corresponding to the cyanocobalamin were plotted versus the concentration of the standards and fitted by least squares linear regression to the following equation (equation 4.1):

Equation 4.1:

$$y = b \cdot x + a$$

In which y is the area of the peak; x is the concentration ($\mu\text{g/mL}$); b is the slope, and a is the intercept with the y -axis. The software Microsoft Excel 2019® was used to perform the calculations.

Linearity has been expressed by the R^2 obtained from the straight line, which represents the linear dependency between the areas and the concentrations.

Sensitivity is defined as the capacity of discrimination between similar concentrations of the same substance. It has been expressed by the significance of the slope and its standard deviation ($b \pm \text{SD}$).

The *Quantification limit* (QL) is the lowest concentration of the substance assayed that can be statistically differentiated from the blank, whereas the *detection limit* (DL) is the minimum amount of substance that can be detected under these experimental conditions. They have been calculated according to the following equations (equation 4.2 and 4.3):

Equation 4.2:

$$QL = \frac{10 \cdot SD}{b}$$

Equation 4.3:

$$DL = \frac{3 \cdot SD}{b}$$

Where *SD* stands for the standard deviation of the intercept, and *b* for the slope of the line.

The *precision* is expressed by the variation coefficient (VC) of the average concentration calculated in intraday and interday assays. Intraday VC (%) was calculated by injecting the different concentrations assayed three times during the same day, while Interday VC (%) was calculated from the areas obtained across three different days.

The *accuracy* was evaluated by the relative error (Er) from the different concentration of the three straight lines analysed across three different days, according to the mathematical expression described in the following equation (equation 4.4):

Equation 4.4:

$$Er (\%) = \frac{(C_{exp} - C\hat{e})}{C\hat{e}} \cdot 100$$

Where *C_{exp}* stands for the experimental concentration, and *C \hat{e}* for the theoretically calculated one.

4.2. Results and Discussion

B12-HPLC analysis under the described conditions resulted in a single and well-defined chromatographic peak with a retention time of 3.5 min. A typical chromatogram is shown in Figure S1 (Annex I).

The relationship between the chromatographic areas and cyanocobalamin concentrations was assessed in the range 10-0.039 µg/mL. The obtained results are summarised in Tables 4.2-4.5.

The linearity of the method is demonstrated by the determination coefficients, being higher than 0.999 in all cases. The graphic representations of the linear regression of the intraday and interday calibration curves are shown in Figures 4.1 and 4.2. The detection and quantification limits of the method were 0.033 µg/mL and 0.11 µg/mL

respectively, calculated from the values obtained for three different curves assayed in three different days.

Table 4.2. Values of cyanocobalamin intraday calibration curve (CC) from 10 to 0.039 µg/mL.

INTRADAY CALIBRATION				
Concentration (µg/mL)	Area (CC1)	Area (CC 2)	Area (CC 3)	Average (mean ± SD)
10	541342	529090	519483	529971 ± 10956
5	285161	282025	277311	281499 ± 3951
2.5	138442	138583	141459	139494 ± 1702
1.25	72673	69718	67483	69958 ± 2603

0.312	23798	24551	25652	24667 ± 932
0.156	12671	12866	13355	13297 ± 405
0.078	7153	7589	7586	7442 ± 250
0.039	3524	3405	3633	3520 ± 114

Table 4.3. Values of cyanocobalamin interday calibration curve (CC) from 10 to 0.039 µg/mL.

INTERDAY CALIBRATION				
Concentration (µg/mL)	Area (CC1)	Area (CC 2)	Area (CC 3)	Average (mean ± SD)
10	541342	529128	558142	535235 ± 14567
5	285161	261533	287887	273347 ± 14492
2.5	138442	130208	143989	134325 ± 6934
1.25	72673	65023	71652	68848 ± 4153
0.625	43213	39014	40799	41113 ± 2107
0.312	23798	22079	20910	22938 ± 1452
0.156	12671	10975	12845	11823 ± 1033
0.078	7153	6131	7057	6642 ± 564
0.039	3024	2596	2989	2810 ± 237

Table 4.4. Average of the slope (b) and intercept (a) of the intraday and interday calibration curves.

	Intraday	Interday
b	52900 ± 1098	54079 ± 1624
a	6419 ± 951	3779 ± 1644

Figure 4.1. Average of the intraday CC with concentration values varying from 10 to 0.039 µg/mL.

Figure 4.2. Average of the interday CC with concentration values varying from 10 to 0.039 µg/mL.

The precision and accuracy of the method was evaluated by the variation coefficient (VC) and the relative error (Er), respectively. Tables 4.5-4.8 show the obtained results. The validation of the method was completely satisfactory since every calculation remained under the 10% threshold, as recommended by OCDE guidelines for validation of a bioanalytical method (565). The validation of the UV-vis spectroscopy method -used in chapter 6 experiments- offered an adequate validation as well, as both share the same detection principle (data not shown).

4.3. Milestone and highlights of chapter 4

Milestone: An analytical HPLC method was developed to quantify B12

- **Highlight 4.1:** Calculated parameters proved the sensibility, accuracy, precision, and robustness of the method.
- **Highlight 4.2:** Detection and quantification limits of the method were below than the usual concentrations in the samples in the different studies, for being therefore an adequate method for this work

Chapter 5

Design, development, and characterisation of cyanocobalamin lipid vesicles

Chapter adapted from **Cyanocobalamin Ultraflexible Lipid Vesicles: Characterization and In Vitro Evaluation of Drug-Skin Depth Profiles**, Guillot AJ, Jornet-Mollá E, Landsberg N, Milián-Guimerá C, Montesinos MC, Garrigues TM, et al. *Pharmaceutics*, 2021; and **Exploration of Microneedle-assisted Skin Delivery of Cyanocobalamin formulated in Ultraflexible Lipid Vesicles**. Guillot AJ, Merino P, Bocchino A, O'Mahony C, Giner RM, Recio MC, et al. *European Journal of Pharmaceutics and Biopharmaceutics*, 2022.

5.1. Materials and methods

5.1.1. Materials

The reagents and materials used are listed in table 5.1.

Table 5.1. Reagents and materials for the preparation and characterisation of cyanocobalamin lipid vesicles.

Reagent / Material	Information	Supplier
Mili-Q Water	Resistance > 18MΩ TOC < 10 ppb	Milipore (Madrid, Spain)
Methanol	HPLC-grade	VWR (Radnor, PA, USA)
Phospholipon 90G®	Soybean Phosphatidyl choline	Lipoid (Steinhausen, Switzerland)
Cholesterol	> 95% purity	Acofarma (Madrid, Spain)
Polysorbate 80	Tween 80®	Thermo Fisher Scientific (Waltham, MA, USA)
Cyanocobalamin	> 95% purity	Acofarma (Madrid, Spain)
NaCl	-	Scharlab (Santmenat, Spain)
KCl	-	Scharlab (Santmenat, Spain)
KH₂PO₄	-	Scharlab (Santmenat, Spain)
Na₂HPO₄	-	Scharlab (Santmenat, Spain)
Sodium dodecyl sulphate	SDS 1% (w/v)	Thermo Fisher Scientific (Waltham, MA, USA)
Ascorbic acid	Crystalline > 99% purity	Sigma-Aldrich (St. Louis, MI, USA)
Ammonium molybdate	Tetrahydrate > 99% purity	Sigma-Aldrich (St. Louis, MI, USA)
Perchloric acid	Aqueous solution 70% purity	Sigma-Aldrich (St. Louis, MI, USA)
Cellulose dialysis membranes	Spectra/Por®, 14 kDa cut-off	Repligen (Radnor, PA, USA)
Lactose	-	Guinama (Valencia, Spain)
Sorbitol	-	Guinama (Valencia, Spain)
Polysulphate membrane	Pore size: 200 and 100 nm	Avestin Inc. (Ottawa, Canada)
MTT reactive	Thiazolyl blue formazan	Sigma-Aldrich (St. Louis, MI, USA)
DMEM medium	Dublecco's Modified Eagle's Medium	Thermo Fisher Scientific (Waltham, MA, USA)
DMSO	-	Sigma-Aldrich (St. Louis, MI, USA)

5.1.2. Methods

5.1.2.1. Preparation of liposomes, transfersomes and ethosomes

Several formulations of liposomes (L), transfersomes (T) and ethosomes (E) were prepared by the classic film-hydration method (Figures 5.1 and 5.2) (236,566). Their quantitative composition, reconstitution conditions, and the methods used to purify them are shown in Tables 5.2-5.4. Three batches of each lipid vesicle type were prepared, blank and loaded with a variable amount of B12 which, depending on the formulation, was added to the organic phase dispersion or included in the liposomal reconstitution solution. The two B12 doses were settled at 0.2% w/w when the drug was incorporated in the organic phase, and 1% when it was incorporated in the aqueous phase. The reason for this is to avoid the bilayer saturation in the first case, which would reduce the vesicle flexibility. The 1% w/v corresponds to the 80% solubility limit of B12 in water. Briefly, Phospholipon 90G® (P90G), cholesterol (P90G:Chol molar ratio 17:1) or surfactants (P90G:Tween 15% w/w), and cyanocobalamin (except in the blank formulations and formulations reconstituted with B12-solution) were dissolved in methanol. The solvent was evaporated using a rotary evaporator (BUCHI R-210, Büchi AG; Flawil, Switzerland) under stirring at 50°C and 100 mbar. The resulting thin film was hydrated by addition of Phosphate buffer saline (PBS) pH 7.4 or B12-solution and then stirred for 1 h at 50°C to obtain a MLV dispersion. The ethosomes were prepared by the Tuitou method (Figure 5.3), dissolving P90G and B12 in ethanol (199). Then, an appropriate amount of water was added at 12 ± 0.5 mL/h in a sealed beaker while stirring (710 ± 5 rpm), in a water bath tempered at 30°C. Concurrently, the option of adding B12 dissolved in the water flow was also explored. The system was kept stirring for 5 min after the addition of the water. Once MLV were obtained, their size was reduced by sonication and membrane extrusion. In the case of liposomes and transfersomes, they were firstly sonicated at 50°C for 2 h (Elmasonic S60H, Elma; Singen, Germany), then cooled down to 4°C and extruded through a 200 µm membrane at 30°C (20 times), using a LiposoFast-Basic Extruder (Avestin;

Ottawa, Canada) (567). Ethosomes were sonicated for 1 h at room temperature and reduced by the same extrusion process. After size reduction, the samples were purified by centrifugation (12800 xg, 30 min) or washed in 2 L PBS at 4°C for 24 h (568,569). The batches were then stored at 4°C protected from light.

5.1.2.2. Determination of particle size, PDI and zeta-potential

Particle size (average diameter) and PDI were measured by means of a Malvern Nano Zetasizer (Malvern Panalytical; Malvern, UK). DLS mode was used to measure the vesicular size and PDI, and laser doppler electrophoresis (LDE) to determine the zeta-potential. The temperature was set at 25°C in all cases. Each formulation was analysed in triplicate (n=3) (570).

5.1.2.3. Determination of phospholipid content of vesicles

The method of Rouser et al. (1970) was used to determine the amount of phosphatidyl choline (PC) incorporated into the different vesicles (344). Briefly, 100 µL of the liposomal aqueous samples was heated at 270°C until complete liquid evaporation, followed by addition of 450 µL of perchloric acid (70% v/v). Next, the mixture was heated to 250°C for 30 min. After cooling down, 3.5 mL of water, 500 µL of ammonium molybdate (2.5% w/v), and 500 µL of ascorbic acid (10% w/v) were added. The mixture was vortexed and incubated at 100°C for 7 min. After the tubes were cooled down, the absorbance was measured at 820 nm (HITACHI U-2900 spectrophotometer, Hitachi High-Tech Corp.; Tokyo, Japan). All formulations were analysed in triplicate (n=3).

5.1.2.4. Determination of the entrapment efficiency

Entrapment efficiency (EE) was determined directly by calculating the amount of B12 encapsulated in lipid vesicle dispersions using the following equation (equation 5.1) (571):

Equation 5.1:

$$EE (\%) = \left(\frac{Q_e}{Q_t} \right) \cdot 100$$

Where Q_e is the amount of B12 encapsulated, and Q_t is the amount of B12 used for batch preparation.

For this, 0.5 mL of lipid vesicles dispersion was incubated for 1 h with a mixture of water:methanol:sodium dodecyl sulphate 1% (45:45:10) to dissolve all the vesicle components (572–574). The final mixture was filtered, and B12 content was analysed by HPLC. All formulations were analysed in triplicate (n=3).

5.1.2.5. Differential scanning calorimetry

DSC was carried out using a DSC 214 Polyma (Netzsch; Waldkraiburg, Germany). Temperature scans were performed from 25 to 225°C at a scan rate of 10°C/min (575). Netzsch Proteus Thermal Analysis 8.0 software (Netzsch; Waldkraiburg, Germany) was used to create baselines and thermograms, and used to determine the glass transition temperatures.

5.1.2.6. Evaluation of lipid vesicle flexibility

The flexibility of the different lipid vesicles was estimated indirectly by extrusion through a 100 nm membrane in cold (399). For this, 500 µL of each formulation was extruded 9 times at room temperature. The final collected volume was also recorded and the relative decrease ratio in particle size was calculated. All formulations were analysed in triplicate (n=3).

5.1.2.7. Vesicle morphology: TEM imaging

A drop of the vesicle dispersion was diluted (1:1000), poured into a copper grid and dried for 4 min. Excess of the dispersion was removed and a drop of phosphotungstic acid solution (2%) was applied and dried for 1 min (576). Vesicles were then visualised by means of transmission electron microscopy using a JEOL JEM 1010 -100kV- equipped with an AMT 8Mpx camera (Jeol Ltd.; Tokyo, Japan).

5.1.2.8. Stability studies

The physical stability of the vesicles was checked weekly for 60 days in terms of size and PDI by DLS. The stability of the vesicle suspension was determined using Turbiscan™ LAB Stability Analyzer (Formulation SA; Toulouse, France) by checking the phenomena of coalescence, flocculation, creaming, sedimentation, and clarification during the 24 h after the suspension was formulated (577). The chemical stability of B12 was assessed by determination of drug content every week for 3 months.

5.1.2.9. Freeze-drying

Lipid vesicles were freeze-dried in absence and presence of lactose and sorbitol as cryoprotective agents. Lactose solutions were prepared at a molar ratio PC/sugar 1:10 and sorbitol was prepared at 2.5% v/v (442,453,578,579). Ethosomes were not lyophilised, as ethanol would be removed through the procedure (281). In all cases, 100 µL of the sample was placed together with 400 µL of cryoprotective agent, or no cryoprotectants, as control, in glass vials. Samples frozen at -80°C (Ultra Low Temperature Freezer U570, New Brunswick Scientific; Enfield, CT, USA) for 24 h and lyophilised for 48 h using a freeze-dryer (LyoQuest HT-40, Telstar; Barcelona, Spain) at -50°C and 0.08 mbar (281). Lyophilised samples were afterwards suspended in PBS and the physical stability was checked in terms of size and PDI by DLS. The chemical stability of B12 was assessed by determination of drug content after freeze-drying.

5.1.2.10. Thermogravimetric assay

TGA was carried out using a TG 209 F3 Tarsus (Netzsch; Waldkraiburg, Germany). Temperature scans were performed from 25 to 200°C at a scan rate of 10°C/min (575). Netzsch Proteus Thermal Analysis 8.0 software (Netzsch; Waldkraiburg, Germany) was used to create baselines and thermograms.

5.1.2.11. Drug release study and kinetic model fitting

In vitro release studies were carried out using static FDC with an effective diffusion area of 1.76 cm². 500 µL of each formulation was added to the donor chamber, and the receptor chamber was filled with 12 mL of PBS pH 7.4 (n=6). A Spectra/Por[®] molecular porous membrane was used to separate donor and acceptor compartments. Both the donor compartment and the sampling port were covered with Parafilm M[®] to avoid leakage and solvent evaporation. Samples of 400 µL were collected at 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 24, 48 and 72 h. At every sampling time, the volume was replaced with pre-warmed PBS to guarantee sink conditions (406).

The released B12 was quantified by HPLC and the cumulative amounts of B12 versus time were calculated. The total drug amount released was calculated according to the previous determination of the drug content and plotted versus time. The release profiles were fitted to different mathematical kinetic models: Higuchi, Korsmeyer-Peppas, Kim, Peppas-Sahlin, zero order and first order. For each case, the AIC was calculated to determine the optimal models to explain the experimental data. The R² of the most accurate model were reported, as an indicator of the proportion of variation of the results that can be explained by the model (415,416).

The Higuchi model assumes that the release process is carried out only by passive diffusion and is governed by the following equation (equation 5.2) (410):

Equation 5.2:

$$\frac{Mt}{M_{\infty}} = k \cdot \sqrt{t}$$

Where Mt is the amount released at time t , M_{∞} is the maximum amount of drug released, Mt/M_{∞} is the fraction of the amount of drug released at time t , and k is the constant that governs the process.

The Korsmeyer-Peppas model or Power-law is described with the following equation (equation 5.3) (411,412):

Equation 5.3:

$$\frac{Mt}{M_{\infty}} = k \cdot t^n$$

Where Mt is the amount released at time t , M_{∞} is the maximum amount of drug released, Mt/M_{∞} is the fraction of the amount of drug released at time t , k is the constant that governs the process and explains the characteristics of the system, and n is the diffusion release exponent. Values of $n < 0.5$ are indicative that the release process is explained by passive diffusion; values of $0.85 < n < 1$ show that the process is governed mainly by relaxation and intermediate values $0.5 < n < 0.85$ indicate the existence of both phenomena (anomalous transport).

As a variation of the Korsmeyer-Peppas equation, Kim et al. (1997) proposed a modification to assess the possible burst effect of the formulation (equation 5.4) (414):

Equation 5.4:

$$\frac{Mt}{M_{\infty}} = k \cdot t^n + b$$

Where b is the parameter corresponding to the burst effect.

The Peppas-Sahlin model considers that release may occur through the processes of passive diffusion and relaxation, each represented by a constant (equation 5.5) (413):

Equation 5.5:

$$\frac{Mt}{M_{\infty}} = k_1 \cdot t^n + k_2 \cdot t^n$$

Where k_1 and k_2 are, respectively, the constants associated to the processes of drug release by passive diffusion and relaxation, and n is the diffusion release exponent.

Representative theoretical models, zero order and first order are described by the following equations (equations 5.6 and 5.7) (409):

Equation 5.6:

$$\frac{Mt}{M_{\infty}} = kd \cdot t$$

Equation 5.7:

$$\frac{Mt}{M_{\infty}} = 1 - e^{kd \cdot t}$$

Where kd is the constant of diffusion release that governs the process.

5.1.2.12. Cellular biocompatibility

5.1.2.12.1. Cell culture

For cell culture, RAW 264.7 cell line was used (ECACC; Salisbury, UK). The cells were maintained in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% foetal bovine serum (FBS), penicillin (100 IU/mL), and streptomycin (100 µg/mL) under a humidified atmosphere of 5% CO₂ and a temperature of 37°C (580,581).

5.1.2.12.2. Proliferation assay and cellular viability

A suspension of cells at a density of $1 \cdot 10^6$ cells/mL was seeded onto 96-well plate (200 µL/well) in DMEM medium supplemented with 10% FBS, penicillin (100 IU/mL), and streptomycin (100 µg/mL) (581). After incubation

of 2 h, the medium was replaced with the same volume of DMEM medium supplemented with 0.5% FBS and exposed for 1 h to 10 μL of each lipid vesicle formulation at different concentrations. Then, the medium was discarded and 100 μL of MTT solution (0.5 mg/mL) was added. Supernatant was discarded after 1 h and blue deposits of coloured metabolite were dissolved in 100 μL of DMSO. Absorbance at 510 nm was measured using a VICTOR³ Multilabel Plate Reader (PerkinElmer; Waltham, MA, USA) (582). Results are shown as percentage of cell viability in comparison to untreated control cells, or cells treated with blank lipid vesicles in case of observing cellular proliferation (equation 5.8).

Equation 5.8:

$$\text{Cell viability (\%)} = \left(\frac{\text{Absorbance sample}}{\text{Absorbance control}} \right) \cdot 100$$

Where *absorbance sample* is the absorbance of cells treated with the formulations, and *absorbance control* is the absorbance of non-treated cells or blank-treated cells, at 510 nm.

5.1.2.13. Statistical analysis

All data processing was performed using Microsoft Excel 2016[®] (Redmond, WA, USA) and SPSS version 22.0[®] (IBM Corp., NY, USA). Data is expressed as the mean \pm standard deviation (SD) unless otherwise stated. As a previous requirement for the statistical tests, normality, homoscedasticity, and sphericity were verified if needed. Normal distribution for each data set was assessed by the Shapiro-Wilk test. Homogeneity of variances was confirmed by the Levene's test. Variances of the differences between all combinations of related groups were checked by the Mauchly's sphericity test. Statistical analysis was carried out using the T-test for simple comparisons, one-way ANOVA for tests with two variables, and two-way ANOVA for tests with three variables. All ANOVA tests were followed by the proper post hoc test. Specifically, the Games-Howell nonparametric test was used in case of heterogeneity of variances. When the homoscedasticity requirement was met, Bonferroni or Tukey

tests were used when the number of comparisons were low or high, respectively. The Gabriel test was used if the number of samples were different between the groups. Statistical differences were considered significant if p-values were below 5% ($p < 0.05$).

5.2. Results and Discussion

5.2.1. Particle size, PDI, zeta potential and phospholipid content

During the lipid vesicle design stage, different factors were considered that could potentially influence their properties, based on previous knowledge about this type of nanocarriers. In this sense, two essential factors are the composition and proportion of components, since they can affect important properties, such as the size, stability or releasing ability of the drug. It is well known that increasing the proportion of cholesterol located in the lipid bilayers, the particle size and the vesicle rigidity also increase (583–585). Considering that one of the main reasons why lipid vesicles improve drug absorption through the skin is their ability to deform and penetrate the cells of the *stratum corneum*, the initial idea was to produce flexible vesicles of the smallest possible size (586,587). For this, a low ratio of cholesterol to phospholipid (molar ratio 1:17) was chosen for conventional liposomes, since it provides small and ultraflexible vesicles with enough stability. Furthermore, 85:15% w/w lipid:surfactant ratio was used since Ahad et al. (2018) demonstrated that it is the most suitable for transdermal delivery using transfersomes based on P90G:Tween 80® (237). Also, different proportions of ethanol have been studied for preparing ethosomes (20-50% w/w). In this case, intermediate concentration (30% w/w) was used because it is the most promising ratio for transdermal absorption purposes, according to the characterisation results (588). The initial results (day 0) of size, PDI, zeta-potential, drug loading and phospholipid content are reported in Tables 5.5-5.7.

In accordance with other works, size measurements were within the expected range for these types of lipid vesicles. Wu et al. (2019) obtained conventional liposomes in a range of 236-374 nm, depending on the percentage of cholesterol included in the formulation (227). The transfersome and ethosome particle dimension obtained in B12 lipid vesicles were smaller than in the one of conventional liposomes, because the presence of the edge-activating substances in the lipid bilayer of the vesicles causes a reduction in the surface tension (281). Transfersome sizes obtained were similar to the values previously reported by Carreras et al. (2020), and ethosome batches reproduced exactly the size described by Touitou et al. (2000), the original research for this vesicle type (30% w/w ethanol content) (199,281).

Size has a relevant impact on drug permeability through the skin. Lipid nanoparticles with a diameter of 300 nm or below can enhance their content permeability into the deeper skin layers because the smaller the size, the higher the transdermal absorption obtained (349). Based on this criterion, all vesicles formulated in this work should be able to deliver B12 in dermal or epidermal viable layers and, consequently, allow its systemic absorption. Specifically, transfersomes and ethosomes were the most promising candidates due to their size, theoretical flexibility properties and drug deposition performance. Moreover, nanoparticles with a size range of around 210 nm, as the obtained ultraflexible vesicles, also have the option to penetrate the skin through the transfollicular route (589).

PDI values as a measure of the variability in size of the particle populations were always below 0.3, which is the suggested cut-off value to consider homogeneous populations in terms of size for lipid-based carriers for drug delivery applications (349,453).

Zeta-potential values of all formulations were negative, as expected, due to the negative charge of the phospholipids. Liposomes showed the strongest charge, probably due to their bigger size and higher phospholipid amount. It has also been reported that the surface charge decreases when

increasing the level of cholesterol in a phospholipid membrane (590). Consequently, the prototypes presented lower values in comparison with other reports where lipid vesicles contain cholesterol in higher proportion (281). Regarding the transfersomes and ethosomes, they present a size reduction (probably because of an edge-activator) which implies a lower concentration in phospholipids, thus reducing the negative charge. These results are consistent with the ranges described by Ahad et al. (2017) and Tuitou et al. (2000), who reported values from -5.91 to -14.0 and 4.6 to -4.3 mV for the same type of transfersomes and ethosomes, respectively (199,236). Nevertheless, none of the prototypes present a value lower than -30 mV, which predicts low long-term stability (420).

5.2.2. Entrapment efficiency

The entrapment efficiency percentage and total amount of encapsulated B12 are graphically presented in Figures 5.4 and 5.5.

Figure 5.4. Entrapment efficiency of conventional liposomes, transfersomes and ethosomes prototypes (expressed as percentage). All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$); n.s. means no statistically significant differences ($p > 0.05$).

Figure 5.5. Total amount of B12 encapsulated in 10 mL of lipid vesicles suspension (expressed as µg). All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$).

Usually, hydrophilic compounds show lower entrapment rates than lipophilic ones. This happens because the entrapment is more efficient if the compound is retained in the phospholipid bilayers, which depends on its primary affinity (571,591). Considering this premise, the obtained entrapment efficiency rates are in the expected range (not up to 40-50%). In addition, the ability of B12 to dissolve in water and methanol could lead to a different location of the drug in vesicle structure, leading to a different entrapment rate (Figure 5.6).

Figure 5.6. a) Thin-film when B12 is added after during the reconstitution stage. b) Thin-film when B12 is added with the phosphatidyl choline.

Arsalan et al. (2020) reported a maximum entrapment efficacy of 40% in B12 liposomes when maximising the amount of lipid included during the vesicle formulation (220). This result is clearly superior to L1 data (Figure 5.4). However, the L2 formulation showed the maximum efficiency in the entrapment process compared to the other prototypes, being significantly higher. The comparison between L1 and L2 analyses the effect of including B12 in each phase, and the result was higher when B12 was added to the lipid one. This comparison also suggests that the location of B12 in lipid vesicles might depend on the phase where the drug is added, which was further studied by DSC studies (Chapter 5, 5.1.7. subsection). The possible influence of differences in the initial dose was also checked by preparing L3 formulation. The poor entrapment efficiency in L3 formulation seems to indicate that lipid vesicles were unsuccessfully produced as a consequence of a destabilisation of the vesicle formation with such strategy. Thus, the L3 prototype was discarded for the rest of the experiments. T1d and T2d presented an entrapment value within the expected range. At this point, the differences between both transfersomes and L2 could be attributed either to the differences in size, which allowed the incorporation of a higher amount of B12 in the L2 vesicle core, or to the purification method used to remove the non-entrapped drug. While liposomal formulations were centrifuged, T1d and T2d were dialysed for 24 h (569). This latter reason is also checked through the EE% and PC% results of T1c and T2c. Both values were lower than expected, probably because of the unsuitability of the centrifugation method for transfersomes. In fact, the supernatant obtained after centrifugation of transfersomes was not completely clear, as it was in the conventional liposomes and contained an important amount of lipid vesicles, as demonstrated by a poor phospholipid recovery. The specific encapsulation efficiency parameter was calculated dividing EE% by PC% (Figure 5.7) (592).

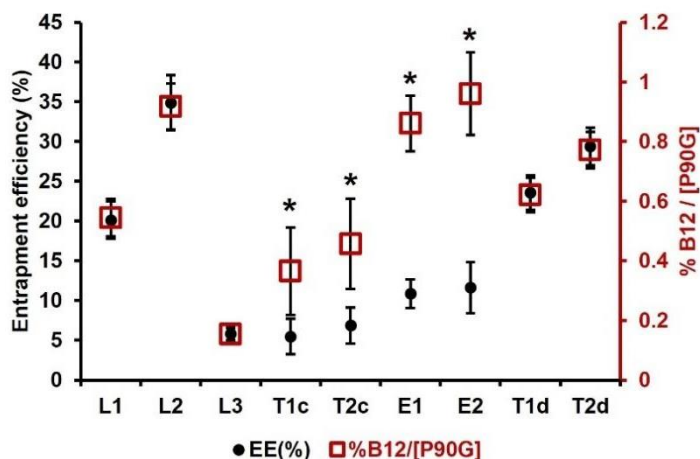

Figure 5.7. Specific entrapment efficiency rate of conventional liposomes, transfersomes and ethosomes prototypes. All results are expressed as mean \pm SD (n=3). * means statistically significant differences (p < 0.05).

Consequently, T1c and T2c prototypes were also discarded for the rest of the experiments. Ethosomes were not dialysed because the dialysis process could extract the ethanol from the vesicles (281). The recovered PC% in ethosomes was around 60% of the initial amount and the EE% was reasonable for a hydrophilic molecule. As the characterisation results of E1 and E2 batches were similar, from this point ethosomal batches were considered similar in terms of characterisation (E1=E2=E3). In the other samples, phosphatidyl choline was not incorporated in a complete manner, presumably due to material loss during the manufacturing and extrusion processes (Tables 5.5-5.7). Therefore, it seems centrifugation was only suitable for liposomal formulations, as the expected amount of phospholipid was recovered after the process. However, it should be considered that the initial objective was to obtain flexible lipid vesicles with the highest possible B12 dose, as saturated systems provide highest skin permeability rates (50). Figure 5.5 represents the final amount of B12 per 10 mL of liposomal suspension. Table 5.8 shows the total amount of B12 incorporated in 1 mL of liposomal suspension. Here, it can be observed that, regardless of the encapsulation efficiency values obtained, the highest B12 load was obtained when B12 was introduced in the aqueous phase in a saturated

PBS solution (L1 and T1d) (Figure 5.5). The higher water volume entrapped by the liposome core contains higher total amounts of B12 compared to the incorporation of the drug in the thin-film layer.

Table 5.8. Entrapment efficiency and total amount of B12 encapsulated.

Formulation	Drug loading (mg per mL)	Entrapment efficiency (%)
L1	1.90 ± 0.31	20.01 ± 2.33
L2	0.75 ± 0.07	37.73 ± 3.45
L3	0.17 ± 0.09	5.82 ± 0.96
T1c	0.52 ± 0.02	5.47 ± 2.21
T2c	0.14 ± 0.04	6.85 ± 2.26
T1d	2.20 ± 0.21	23.6 ± 2.17
T2d	0.60 ± 0.02	30.31 ± 0.95
E1	0.22 ± 0.03	11.62 ± 2.21
E2	0.23 ± 0.04	16.87 ± 1.78
E3	Not applicable	Not applicable

5.2.3. Vesicle morphology: TEM imaging

The vesicle structure and size were assessed by TEM imaging, which has been reported to be a useful method for lipid vesicle visualisation (Figure 5.8). Multilamellar vesicles were observed, since it has been reported that the thin-film method tends to produce heterogeneous vesicles in relation to lamellae number (269). They present spherical-like shapes, although certain irregularity and ovoid-like shapes can be observed due to the drying sample process. Particle size satisfactorily meets the values reported by DLS measurements, however slight variations in size estimations can occur because of the sample preparation mentioned above (dehydration, drying).

Figure 5.8. Representative TEM images of B12 lipid vesicles:
a) liposomes; b) transfersomes; c) ethosomes.

5.2.4. Evaluation of lipid vesicle flexibility

Following Jain et al. (2003), the vesicle size reduction rate and volume loss after cold extrusion was used as an indirect measurement of the vesicles deformability capacity (399). Results are presented in Figures 5.9 and 5.10. Significant differences were obtained between liposomes and ultraflexible vesicles, as expected (593,594). Liposomes were retained in the 100 nm filters and forced to split into smaller particles to pass the pores. Conversely, transfersomes and ethosomes -whose initial size was higher than 100 nm-, maintained their size during the passage thanks to their flexibility. Similarly, the final volume collected after cold extrusion is inversely related to the vesicle flexibility. As such, no differences were observed in transfersome or ethosome batches, while all liposomal prototypes presented a significant reduction compared to their initial volumes. Thus, both techniques confirm the flexibility of transfersomes and ethosomes.

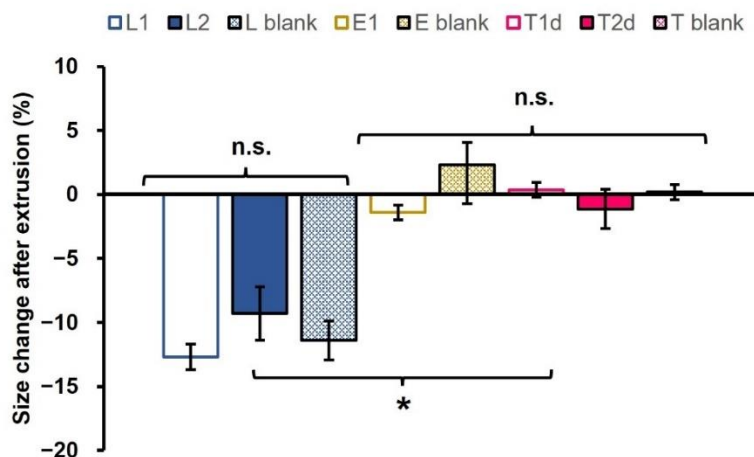

Figure 5.9. Size change after extrusion through 100 nm membrane. All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$); n.s. means no statistically significant differences ($p > 0.05$).

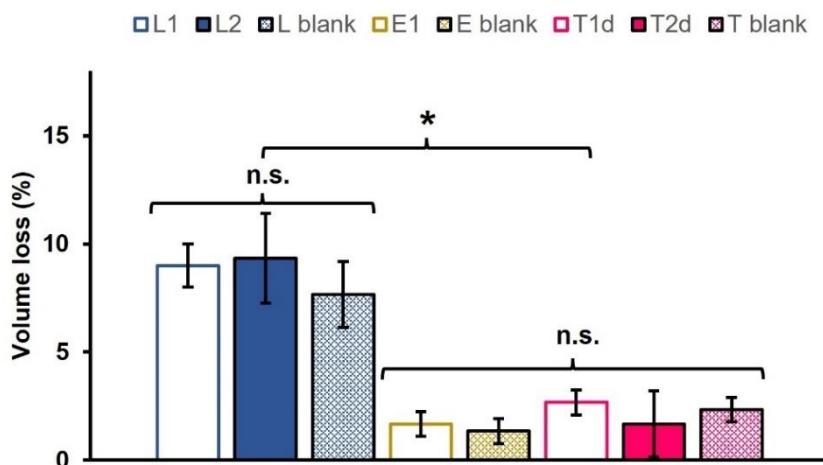

Figure 5.10. Volume loss after extrusion through 100 nm membrane. All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$); n.s. means no statistically significant differences ($p > 0.05$).

5.2.5. Stability studies

5.2.5.1. Short-term stability

The short-term stability behaviour of the formulations was studied by the TSI, a parameter offered by the Turbiscan® LAB Stability Analyzer device. TSI allows the comparison of samples that present different progression phenomena (595). Transfersomes were found to be the most stable formulation, since no changes in light transmission nor backscattering lines were reported over 24h (Figure 5.11). A flocculation phenomenon was observed for the ethosomal samples through the backscattering graph (Figure 5.12). Its evolution over the whole height of the sample proves a global increase of the particle size). Flocculates could be easily redispersed by gentle shaking. Other aggregative processes, such as coalescence, were discarded, given that no significant long-term size changes were observed after periodically redispersing the samples (Chapter 5, 5.2.5.1. subsection; Figure 5.15). Nevertheless, liposomal vesicles experienced first a sedimentation process, as the backscattering increases at the bottom of the sample, due to an increase of the concentration in the dispersed phase (sediment) and a decrease at the top

of the sample, due to a reduction of the concentration (clarified layer) (Figure 5.13). Also, the smallest particles that remained at the clarified phase showed a tiny flocculation at the end of the investigated times (yellow-red frame). Transmission and backscattering profiles in the work of Cristiano et al. (2019) were similar, and showed comparable phenomena of flocculation for ethosomes and stability for transfersomes (596).

T: transmittance; BS: backscattering.

Figure 5.13. Conventional liposomes (L1) short-term stability behaviour. T: transmittance; BS: backscattering.

Therefore, the global destabilisation kinetics (Figure 5.14) confirmed the stability indexes about B12 vesicles (conventional liposome < ethosome < transfersome).

Figure 5.14. Global destabilisation kinetics. L1 TSI (blue); T1d TSI (red); E1 TSI (yellow).

5.2.5.1. Long-term stability

Physical and chemical long-term stability was monitored by measuring the vesicle size, PDI and EE% every week for 2 months and the drug content for 3 months. Figure 5.15 shows no significant differences in size, as a function of storage time at 4°C, except for the liposome formulations after 4 weeks of storage. This fact has previously been

reported by other authors (426,428). On the other hand, intra-type significant changes in PDI were not observed, pointing out a homogeneous evolution in size of vesicles populations (Figure 5.16).

Figure 5.15. Vesicle size over 2 months of storage (4°C). All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$).

Figure 5.16. PDI over 2 months of storage (4°C). All results are expressed as mean \pm SD (n=3).

Significant changes in drug content related to the initial amount were detected in all prototypes between weeks 7 and 8 (Figure 5.17). Recent works have also reported a drug leakage and an effective content loss, especially for liposomes containing hydrophilic drugs, thus supporting our observations (334,428). Considering these findings, B12 lipid vesicles seem to exhibit short and medium-term stability (at least 1 month for all the parameters checked), which makes them suitable for clinical applications. However, to increase the stability for longer-term use, liposome lyophilisation has also been investigated for these B12 lipid vesicles, since it has been shown to be an excellent method for ensuring liposome long-term stability (452,597).

Figure 5.17. Remaining percentage of B12 amounts during 2 months of storage (4°C). All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$).

5.2.6. Freeze-drying

Long-term stability is one of the biggest challenges for liposome and modified-lipid vesicle production because lipid-based particles can be easily oxidised (430). When dispersed in an aqueous solution, they remain stable for between 2-3 months (79,427), although size changes could take place

from the first month (426,428). As far as physical instability is concerned, the developed B12-conventional liposomes have shown significant size changes after 1 month at 4°C storage (Figure 5.15) (79). Moreover, a significant and progressive drug leakage occurred from week 7 (Figure 5.17), as is usual for lipid vesicles containing hydrophilic drugs (428). These facts are in accordance with the zeta-potential values obtained, which did not predict long-term stability. Figure 5.18 shows pictures of the lyophilisation result using different cryoprotective agents.

Figure 5.18. Representative photographs of freeze-dried B12-lipid vesicles: a) blank liposome-lactose; b) blank liposome-sorbitol; c) B12 liposome-lactose (L1); d) B12 liposome sorbitol (L1); e) blank transfersome-lactose; f) blank transfersome-sorbitol; g) B12 transfersome-lactose (T1d); h) B12 transfersome-sorbitol.

Visual inspection denotes that the use of sorbitol derived into a collapsed cake and a sub-optimal final product (Figures 5.18 b, d, f and h) (452). This collapse process implies only minor or cosmetic irregularities which do not impact patient safety or product efficacy (444,452). This way, sorbitol was considered a non-optimal cryoprotectant. Conversely, lactose achieved a uniform product with no evidence of damage (Figures 5.18 a, c, e and g). The main difference between lactose and sorbitol, regarding

lyophilisation-related properties, is their glass transition temperature of maximum freeze concentrate (T_g), while the collapse temperature (T_c) is much closer (-32°C and -27°C for lactose and sorbitol, respectively). As reported by Skrabanja et al. (1994), lactose T_g is -28°C and sorbitol presents a T_g of -43°C (598). Collapse may occur when the product temperature exceeds the T_g during the primary drying, which corresponds to the sublimation process forced by the pressure decrease, or the T_c during the early secondary drying, which refers to the residual water desorption process triggered by the product temperature increase under low pressure (444). This data indicates that the problem with the sorbitol-containing samples was probably that the freeze-drying equipment did not maintain a low enough temperature during the primary drying, since the temperature was settled at -50°C just below the T_g of sorbitol, and the safety margin was not guaranteed during the whole process.

Lyophilised lipid vesicles were then redispersed in water and their physical stability was assessed by size and PDI measurements. Figures 5.19 and 5.20 show the size and PDI results before and after freeze-drying. As mentioned above, the study only included liposomes and transfersomes, because ethosomal vesicles cannot be freeze-dried without ethanol loss. The results obtained show significant differences between the protected and the unprotected formulations. In terms of size, no significant differences were found when using lactose or sorbitol for transfersomes (Figure 5.19). However, a significant decrease was observed in liposomal formulations (L1 and L2) in comparison to non-freeze-dried liposomes. This event has previously been reported by different studies, where the use of high saccharide concentration leads to a size decrease after lyophilisation (441,453). Several reasons have been suggested to explain this phenomenon, but none have been generally accepted since cryoprotectants can act by different mechanisms. The water replacement theory suggests that cryoprotectants replace the water molecules that surround the particles, thus stabilising the vesicles from water removal (441,454,599). However, kosmotropic effects of stabilising excipients

support that the damage during the freeze-drying process is prevented because of a lower content in water at the membrane interface (454). This idea fits correctly with the reported findings, since the reduced size can be derived from a lower water entry into the liposomes after reconstitution. Lyophilised-lactose transfersomes did not show any differences with the non-freeze-dried formulations, probably due to their smaller initial size. Sorbitol was revealed as an ineffective cryoprotective agent for transfersomes, as size results evidenced a significant size increase after the process. Therefore, in this case, the collapsed cake suggests a loss of the 3D structure of the vesicles during the process.

Figure 5.19. Vesicle size before and after freeze-drying process. All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$).

Figure 5.20. Vesicle PDI before and after freeze-drying process. All results are expressed as mean \pm SD (n=3). * means statistically significant differences ($p < 0.05$).

Non-use of cryoprotective agents led to a typical significant increase in population heterogeneity, as shown by the PDI values (Figure 5.20) (453). The mechanical stress produced by the freezing process was properly softened by using lactose, which was able to maintain a homogeneous size distribution in all vesicles. In this sense, it is possible that the sugar molecules play a stabilising role, considering that they would help to maintain the lateral spacing between the phospholipids, as membrane stabilisers (600). In contrast, PDI values increased remarkably in liposomes and transfersomes. As discussed above, the collapse experienced by sorbitol batches could bring critical consequences to sample integrity and be responsible for this behaviour (444).

5.2.7. Thermogravimetric analysis

The quality of freeze-dried powders was assessed by the determination of the residual water content, which must be lower than 3%. Thermal analysis determines the remaining percentage of sample weight as function of the heat transfer (Figures 5.21 and 5.22).

Figure 5.21. Thermogravimetric analysis of freeze-dried liposomes (L1).

Figure 5.22. Thermogravimetric analysis of freeze-dried transfersomes (T1d).

As water evaporates at 100°C, the weight loss in the first steps corresponds to residual water content, which was around 1% in both cases.

5.2.8. Differential scanning calorimetry

As reported before, the physicochemical properties of B12 allow its incorporation into the liposomal system dissolved either in the reconstitution solution or with the lipidic components before the organic solvent removal. This observation, linked to the differences in entrapment efficiency results, suggests a possible different liposomal assembly or structure depending on the cyanocobalamin addition step. In order to elucidate this fact, a DSC study was performed. DSC allows us to determine different thermodynamic parameters like glass transition temperature (T_g), degradation temperature (T_d), melting temperature (T_m) or crystallisation temperature (T_c) of a powder sample or solid residue (461). While T_d , T_m and T_c are transitions characterised by the absorption or release of latent heat carried out during the isothermal changes of matter (462), glass transition temperature (T_g) is defined as the change associated with variations in the molecular mobility

and relaxation time in amorphous solids, and is considered the change in the direction between the rubbery and the glassy states (601), where the latent heat and volume of the system remain constant (461).

Figures 5.23-5.27 show the thermogram of the two types of B12 and lipid vesicles that can be lyophilised and therefore studied in powder form (liposomes and transfersomes). The temperature and acquired signal are plotted in the x and y-axis, respectively. First order transitions (crystallisation, melting and degradation) are observed as well-defined peaks. At high temperatures, the system decreases its viscosity and melts. Further energy produces the degradation of the product (461). The main inconveniences of this technique are, the difficulty when analysing multicomponent preparations, and the overlapping of different signals when high heat rates are used, or weak signals when low heat rates are used (602). In this case, a 20°C/min heat rate was used even though melting and degradation are observed together.

The obtained thermograms showed a very different degradation between liposomes and transfersomes, whereas no significant differences were noticed in the degradation profiles, due to the different phases of incorporation of the drug. While L1 and L2 present two clear signals (Figures 5.24 and 5.25), before and after 160-170°C, T1 and T2 only present the complex peak of degradation after 160-170°C (Figures 5.26 and 5.27). Usually, the different coating or interaction between the components of a formulation leads to different DSC profiles (603). Analysis of the different main lipid vesicles ingredients (data not shown) results in the obtention of a peak at 150°C for cholesterol, which can be clearly observed in liposome thermograms (Figures 5.24 and 5.25), whereas the phospholipid analysis showed a glass transition temperature of around 55°C because of its amorphous solid nature. B12 DSC showed a peak at around 250°C corresponding to its melting temperature (Figure 5.23). Therefore, these profiles suggest a different component assembly between both types of vesicles and as such, different vesicle structure and

properties. Moreover, there is no evidence, which implies that the incorporation of B12 in a determined phase leads to a different drug location into the vesicles and, consequently, the differences observed in the entrapment efficiency are not produced due to the drug location. It has been suggested that amphiphilic molecules that can be solubilised in organic and aqueous phases are partially embedded in the lipid bilayers and the rest in contact with the aqueous core (324). Therefore, the higher entrapment rates shown by L2 and T2 vesicles, could be produced because their encapsulation is facilitated as all the incorporated drug is surrounding and maintaining an intimate touch with the lipids, which does not happen when it is solubilised in the reconstituting solution (L1 and T1 vesicles).

Figure 5.27. Thermogram obtained from the analysis of T2d.

5.2.9. Drug release study

In vitro drug release studies are regularly used in the optimisation process of pharmaceutical forms (604). The cumulative drug release profiles of the formulations were estimated by a dialysis method using the FDC set-up and presented in Figure 5.28 and 5.27 (605).

Figure 5.28. Release profiles from liposomes (L1 and L2), transfersomes (T1c, T2c, T1d, and T2d), ethosomes (E1), and B12 solution after 72 h.

* means statistically significant differences ($p < 0.05$); n.s. means no statistically significant differences ($p > 0.05$).

Figure 5.29. Release profiles from liposomes (L1 and L2), transfersomes (T1c, T2c, T1d, and T3d), ethosomes (E1), and B12 solution after 8 h.

* means statistically significant differences ($p < 0.05$).

The B12 solution (S) was used as a control as it represents the drug diffusion profile without limitations. The rest of the lipid vesicle formulations showed a controlled release of the drug, as shown in Figure 5.29. The B12 release was faster during the initial hours from all the tested formulations due to the concentration gradient established between the donor and the receiver media (606). After 3 h, the amount of B12 detected in the receptor medium is significantly higher for the solution than the liposomes, transfersomes and ethosomes, as expected (607). Moreover, differences between the release from liposomal and ultraflexible vesicles were also observed, with it being lower from the liposomes, probably due to their different rigidity. It has been reported that vesicles with considerable bilayer rigidity exhibit higher resistance to drug transport through the liposomal bilayer (229). It is probably that the long-term percentage of the drug released is also affected by this vesicle property. The lowest percentage of the drug released corresponds to the liposomes and the highest to the ethosomes, which were able to release around 100% of the encapsulated B12. Nevertheless, the final percentages of released B12 between transfersomes and ethosomes were different (Figure 5.28), even though no differences were found in vesicle flexibility during the characterisation stage. Possible reasons for this are: the difference of entrapped drug amounts (higher in transfersomes than in ethosomes) that led to different gradients, and the vesicle structure and components. Similar results were found in B12 release from L1 and L2 formulation profiles at the initial stage (<10 h) even though the amount of B12 entrapped in L1 is higher than L2 formulation. Differences are observed when reaching the plateau. However, the cumulative amounts of B12 found in the last L1 samples (44%, 46% and 48% at 24, 48 and 72 h, respectively) rise, suggesting that the plateau has still not been reached and differences may be reduced if the release is extended.

5.2.10. Kinetic model fitting

The experimental release data were fitted to different kinetic models to better understand the release profiles: Higuchi, Korsmeyer-Peppas, Kim, Peppas-Sahlin, zero order and first order. This point is highly recommended since mathematical modelling could help to understand the further *in vivo* performance of the formulations (608). Fitting parameters of all the models using the first 10 h-data and 72 h-data are listed in Tables S1-S12 (Annex II). The AIC was used as a comparative of the goodness of fit (also listed in Tables S13 and S14, Annex II). In general, the Korsmeyer-Peppas model presented the lowest AIC values, indicating an accurate fitting, for almost all formulations. However, in certain cases (T1d 10 h, T2c 72 h, E1 72 h and S), the first order was the best model. The Kim model is a modification of Korsmeyer-Peppas, which considers a possible burst effect. This burst effect (represented by parameter “b”) was neglected by the fitting, and the results of both models match. Burst release effect of drugs is frequently related to “dose dumping”, an event to avoid in a controlled release system that is demonstrated not to happen in the developed prototypes (609,610).

Contrary to what was expected for ultraflexible vesicles, the Korsmeyer-Peppas model was more suitable for most of the cases, pointing out that they present a mixed release mechanism. It seems that relaxation has a stronger influence during the first steps and gets diluted during longer sampling times, in favour of passive diffusion. This behaviour can be deduced from the values of the release exponent “n” which presents intermediate values (0.5-0.85) when the initial 10 h-data is fitted, and low values (<0.5) when 72 h-data is included. Finally, the R² values from both models are also listed in Tables S17 and S18 (Annex II). We could observe from their analysis that the models used are suitable for explaining the release process (they account for > 90% of the experimental data variation) (415,416).

5.2.11. Cellular biocompatibility

Lipid nanocarriers are well-known as promising candidates to enhance the transdermal delivery of drugs, due to their excellent biocompatibility and ease of mixing with skin lipids (611). In certain cases, they have even shown better biocompatibility than the equivalent drug solutions (491). Biocompatibility of liposomal formulations has been tested previously in the RAW 264.7 cell line (473,474). Cell viability, expressed as percentage, is shown in Figures 5.30-5.32. Percentages above 80% were considered non-toxic and below 80% were considered cytotoxic (478).

Figure 5.30. RAW 267.4 cell viability by MTT test after 24 h of treatment with liposomes (L blank, L1 and L2).

Figure 5.31. RAW 267.4 cell viability by MTT test after 24 h of treatment with transfersomes (T blank, T1d and T2d).

Figure 5.32. RAW 267.4 cell viability by MTT test after 24 h of treatment with ethosomes (E blank and E1).

The obtained data demonstrates a direct connection between the cell viability and the B12 dose-lipid carrier association. The non-diluted blank formulations showed a cell proliferative effect, especially notable in liposomes and transfersomes. This effect is one of the main inconveniences of MTT assay for testing lipid vesicles, since certain vesicle components can stimulate cell growth (479). For this reason, cell survival rates were recalculated according to the proliferation produced by each vesicle type after 24 h. Considering that high-loaded vesicles could lead to cytotoxic effects in cells (612,613), and blank formulations had been revealed to be completely biocompatible, it seems clear that an excessive dose of B12 is mainly responsible for the observed cell death. However, the loss of cell viability could also be affected by the lipid carrier, as they provide a completely different drug release pattern and properties. For example, it should be noted that toxic concentration in liposomes and transfersomes differ from L1 and T1 to L2 and T2 respectively, with the formulations where cyanocobalamin was added in the lipid phase being more biocompatible, and is theoretically more integrated within the lipid bilayers. As Figures 5.30 and 5.31 show, the less biocompatible formulations were the liposomes, while the ethosomes were highly biocompatible. Ethosomes did not show any sign of toxicity with the initial B12 dose (1.3 mg/mL). Mönkkönen et al. (1994) stated that negatively charged vesicles provided an effective drug

delivery to cells, while neutral ones were unable to deliver their content (614). As B12 liposomes showed 2-fold lower zeta-potential values in comparison to ethosomes, they could easily lead to dose-related side-effects for cells. Transfersomes were shown to be intermediately cytotoxic carriers, as T2 vesicles presented higher cell viability than L2 with similar B12 dose. Moreover, Sguizzato et al. (2021) observed that Tween-containing vesicles induced greater cytotoxic effects in comparison to ethosomes, which did not contain any surfactant as edge activator (615), which supports the higher biocompatibility results obtained by the ethosomes here. Finally, it should be kept in mind that skin B12 concentrations will presumably be lower than those assayed in this cell viability assay and therefore, no issues of biocompatibility are expected with B12 lipid vesicle formulations in the clinic.

5.3. Milestone and highlights of chapter 5

Milestone: Three types of lipid vesicles were designed, produced and characterised: liposomes, transfersomes and ethosomes.

- **Highlight 5.1:** Size and PDI of the developed lipid vesicles were optimal for transdermal delivery purposes, being < 300 nm and < 0.3 respectively. Measurements obtained by DLS and SEM were in accordance.
- **Highlight 5.2:** Transfersome and ethosome flexibility was confirmed by neglectable size reduction and volume loss ratios after cold extrusion.
- **Highlight 5.3:** Entrapment efficiency was in the expected range for a hydrophilic drug. Final drug cargo was inversely proportional to entrapment efficiency, with the less efficient prototypes being those that contained the highest amount of drug.
- **Highlight 5.4:** Zeta-potential values were not predictive of long-term stability (liposomes < transfersomes < ethosomes). However, to preserve them during long-storage periods of time, freeze-drying

was successfully applied to conventional liposomes and transfersomes when lactose was used as a cryoprotective agent.

- **Highlight 5.5:** As a consequence of the short-term stability, it was concluded that centrifugation was an optimal method to purify liposomes, whereas transfersomes were satisfactorily purified by dialysis. Finally, ethosomes were neither centrifuged or dialysed, as they were not sedimented and ethanol could be removed as a consequence of its solubility in aqueous medium.
- **Highlight 5.7:** Drug release studies concluded that within the initial 10 h, relaxation is the main mechanism, whereas diffusion contributes to the release after this release time.
- **Highlight 5.8:** Biocompatibility of lipid vesicles was assessed using the RAW 264.7 cell line. Ethosomes showed a high biocompatibility in comparison to conventional liposomes and transfersomes, as previous reports indicate that cellular uptake of nanoparticles increases with negatively-charged surface properties.

Chapter 6

**Design, development, and characterisation
of cyanocobalamin dissolving microneedles**

6.1. Materials and methods

6.1.1. Materials

The reagents and materials used are listed in table 6.1.

Table 6.1. Reagents and materials for the B12 MNA preparation.

Reagent / Material	Information	Supplier
Distilled water	-	-
Cyanocobalamin	> 95% purity	Acofarma (Madrid, Spain)
NaCl	-	Scharlab (Santmenat, Spain)
KCl	-	Scharlab (Santmenat, Spain)
KH₂PO₄	-	Scharlab (Santmenat, Spain)
Na₂HPO₄	-	Scharlab (Santmenat, Spain)
PVA 9-10, 38-50 kDa	Poly (vinyl alcohol)	Sigma-Aldrich (St. Louis, MI, USA)
PVP 40 kDa	Poly (vinyl pyrrolidone)	Sigma-Aldrich (St. Louis, MI, USA)
PMDS moulds (15x15)	600H:200B nm (H: height B: base)	Micropoint Technologies (Singapore)

6.1.2. Methods

6.1.2.1. Preparation of cyanocobalamin dissolving MNA

Several dissolving MNA were prepared by the solvent casting method using poly (vinyl alcohol) (PVA) and poly (vinyl pyrrolidone) (PVP) as biocompatible polymers. Their quantitative composition is shown in Table 6.2. The MNA preparation process is illustrated in Figure 6.1. Firstly, polymers were dissolved in water to prepare stock blends, which were used to prepare the gels at the desired polymer concentration. The gels were mixed with B12 or lyophilised T1d lipid vesicles until homogeneous. Then, the blends were centrifuged (3500 rpm, 15 min) to remove air bubbles and 0.25 g was poured into the polydimethylsiloxane moulds. Following this, the moulds were placed in a positive pressure chamber (Protima[®] pressure tank, TÜV Rheinland; Cologne, Germany). To fill the cavity of the moulds with the gels, a pressure of 3-4 bar was applied for 45 min (616). Finally, the microneedles were dried at room temperature for 24-48 h and removed from the moulds.

Figure 6.1. Manufacturing process of dissolving MNA.

Table 6.2. Quantitative composition of the different B12 MNA.

Dissolving microneedle formulation	Composition (% w/w)				
	PVA 9-10 kDa	PVA 38-50 kDa	PVP 40 kDa	B12	T1d F-D
F1	15	-	5	1	-
F2	15	-	12.5	1	-
F3	15	-	20	1	-
F4	30	-	-	1	-
F5	-	15	5	1	-
F6	-	15	12.5	1	-
F7	-	15	20	1	-
F8	-	30	-	1	-
F9	-	-	30	1	-
F10	15	-	5	-	10
F11	-	15	5	-	10

6.1.2.2. Microneedle morphology: SEM imaging

The morphology of the microneedles was observed using SEM (EVO LS 15 SEM, Carl Zeiss; Jena, Germany). For this, MNA were coated with a conductive gold layer (Q150 RS sputter coater, Quorum Technologies, Lewes, UK) (617).

6.1.2.3. Mechanical strength and insertion properties of MNA

Mechanical strength of MNA was evaluated using a TA-TX plus Texture Analyser (Stable Microsystem; Haslemere, UK). MNA were briefly visualised before testing using a light microscope (Leica ICC50 HD, Leica Microsystems; Wetzlar, Germany) and then carefully placed on the flat plate of the equipment with the needles pointing downwards. The compression mode was applied with a force of 32 N/m for 30 sec to compress the MNA against a stainless-steel surface. Finally, MNA were observed under the light microscope to compare the decrease in size of the needles (Figure 6.2) (618).

Figure 6.2. Standard mechanical test procedure.

The insertion depth of MNA was determined using an artificial skin model. A similar mechanical test set-up was used but MNA were pressed against eight layers of Parafilm M[®] (Figure 6.2). The holes created in each layer were counted using a light microscope (619).

Figure 6.3. Parafilm M[®] artificial skin model to determine microneedle insertion depth.

6.1.2.4. Thermogravimetric analysis

TGA was carried out using a TG 209 F3 Tarsus (Netzsch; Waldkraiburg, Germany). Temperature scans were performed from 25 to 200°C at a scan rate of 10°C/mim (575). Netzsch Proteus Thermal Analysis 8.0 software (Netzsch; Waldkraiburg, Germany) was used to create baselines and thermograms.

6.1.2.5. Differential scanning calorimetry

DSC was carried out using a DSC 214 Polyma (Netzsch; Waldkraiburg, Germany). Temperature scans were performed from 25 to 225°C at a scan rate of 10°C/min (575). Netzsch Proteus Thermal Analysis 8.0 software (Netzsch; Waldkraiburg, Germany) was used to create baselines and thermograms, and to determine the glass transition temperatures.

6.1.2.6. Drug release study and kinetic model fitting

In vitro release studies were carried out dissolving the MNA in PBS. For this, they were placed into a 12-well plate filled with 5 mL of PBS with a temperature of 37°C (n=3). Samples of 200 µL were collected at 5, 10, 15, 20, 30, 40, 50, 60, 90, 120, 180, and 240 min. At every sampling time, the volume was replaced with pre-warmed PBS to guarantee sink conditions (Figure 6.4) (620).

Figure 6.4. Scheme of the drug release experiment from dissolving MNA.

The released B12 was quantified by UV-Vis spectroscopy and the cumulative amounts of B12 versus time were calculated. The total drug amount released was calculated according to the previous determination of the drug content and was plotted versus time. The release profiles were fitted to the Korsmeyer-Peppas as it considers the passive diffusion and polymer erosion as possible drug release mechanisms. In this model,

values of release exponent $n < 0.5$ are indicative that the release process is carried out by polymer diffusion/dissolution; values of $0.85 < n < 1$ show that the process is mainly governed by relaxation/swelling and intermediate values $0.5 < n < 0.85$ indicate the existence of both phenomena. The possible burst effect was checked using the modification proposed by Kim. Both kinetic models are described in the equations 5.3 and 5.4 (Chapter 5, 5.1.2.8. subsection).

6.1.2.7. Statistical analysis

All data processing was performed using Microsoft Excel 2016® (Redmond, WA, USA) and SPSS version 22.0® (IBM Corp., NY, USA). Data is expressed as the mean \pm standard deviation (SD) unless otherwise stated. As a previous requirement for the statistical tests, normality, homoscedasticity, and sphericity were verified if needed. Normal distribution for each data set was assessed by the Shapiro-Wilk test. Homogeneity of variances was confirmed by the Levene's test. Variances of the differences between all combinations of related groups were checked by the Mauchly's sphericity test. Statistical analysis was carried out using the T-test for simple comparisons, one-way ANOVA for tests with two variables, and two-way ANOVA for tests with three variables. All ANOVA tests were followed by the proper post hoc test. Specifically, the Games-Howell nonparametric test was used in case of heterogeneity of variances. When the homoscedasticity requirement was met, Bonferroni or Tukey tests were used when the number of comparisons were low or high, respectively. Gabriel test was used if the number of samples were different between the groups. Statistical differences were considered significant if p-values were below 5% ($p < 0.05$).

6.2. Results and Discussion

6.2.1. Preparation of cyanocobalamin dissolving MNA

Aqueous dispersions of different biocompatible polymers were used either alone or in combination to prepare the dissolving MNA prototypes. PVA (9-10 kDa), PVA (38-50 kDa) and PVP (40 kDa) were the selected polymers, as indicated in Table 6.2. In addition, different concentrations of freeze-dried lipid vesicles were also utilised to produce a total of eleven MNA prototypes. Two formulations, F8 and F10, did not produce optimal MNA. The first one contained an excessively viscous polymer blend (30% of high-molecular weight PVA) that did not allow gel pouring into the needle moulds. The second one contained the freeze-dried lipid vesicles into the gel formulation. In this case, the low-molecular weight PVA (15% w/w) was unable to retain the lipid vesicles in the polymeric network after the centrifugation before the casting step to remove the air bubbles. Furthermore, the lipid vesicles migrated to the upper fraction of the polymeric blend as a consequence of the low density of the lyophilised powder. The rest of the formulations produced homogeneous polymer mixtures (Figure 6.5), and the resultant MNA exhibited sharp needle tips upon visual examination under light microscope.

Figure 6.5. Image of B12-loaded MNA.

6.2.1.1. Thermogravimetric analysis

MNA exhibited a discrete flexible behaviour after array demoulding. One week later, MNA were completely resistant to deformation and achieved their full strength and insertion properties. This fact was monitored by TGA analysis which showed that MNA lost a lower percentage of weight seven days after production, when compared to the recently demoulded MNA. Different TGA of representative MNA prototypes are presented in Figures 6.6-6.9. The most likely reason for this behaviour is that after 48 h the drying process is incomplete, conferring a certain degree of flexibility as the final polymer chain interactions are not completely established and polymers are more sensitive to heat degradation. Specifically, a temperature of 200°C produces weight loss of around 7-9% and 12-14%, respectively. As a consequence, the rest of the studies involving MNA were performed after a convenient storage period.

Figure 6.9. Lipid vesicle prototype (F11): day 0 (purple) and day 7 (green).

6.2.1.2. Differential scanning calorimetry

MNA were characterised based on their constitutive materials in order to study possible polymer-polymer or polymer-drug interactions and characterise them for further scalability-processes. Depending on the main component, the thermograms showed a particular profile. The PVP-based prototype (F9) showed a considerable signal in the 50-150°C range (Figure 6.10). This wave was also observed in the PVA 9-10 kDa-based formulations, where a notable depression was found in the baseline after around 200°C (Figure 6.11). Finally, PVA 38-50 kDa-based formulations completely hid the PVP signal, probably as a consequence of the huge influence that this polymer exhibits in the MNA molecular structure. In addition, a recurrent peak was seen at 210-220°C which depends on the polymer concentration, as the higher concentration, the higher the peak intensity (Figure 6.12).

Figure 6.12. Thermogram obtained from the analysis PVA 38-50 kDa-based prototypes: F5 (gold), F6 (purple), F7 (blue), and F11 (green).

6.2.2. Microneedle morphology: optical microscopy and SEM

Representative SEM images of free drug and freeze-dried lipid vesicle-loaded formulations are presented in Figures 6.13-6.16. Two main differences can be observed between them. First, B12-loaded MNA present a smooth topography, whereas freeze-dried lipid vesicles interact with the MNA surface leading to an irregular relief. Second, the needle height of lipid vesicle-loaded MNA was significantly lower than the other MNA prototypes ($p < 0.05$). F1-F10 needle height ranged between 0.45-0.4 μm , whereas F11 was $0.31 \pm 0.02 \mu\text{m}$ (Chapter 6, 6.2.3 subsection; Figure 6.20). It is probable that the high lipid-vesicle content (10% w/w) produces a different polymer behaviour with a greater trend to contraction in comparison to that produced by the free-drug (1% w/w) in the other MNA. Needle height determinations by optical microscopy were consistent with the SEM measures (Figure 6.17).

6.2.3. Mechanical strength and insertion properties of MNA

The ability of MNA to effectively insert into the skin is crucial to its efficacy because they must completely penetrate the *stratum corneum* to deliver their 'cargo'. Mechanical strength evaluation was carried out to determine the capability of MNA arrays to resist the applied compression force when inserted into the skin. The mechanical strength of MNA was determined based on the percentage of height reduction of the needles on the arrays after the application of a force of 32 N/array, similar to manual compression force (619). The results of this experiment are presented in Figures 6.18 and 6.19. The compression of MNA produced a significant needle height reduction in all cases ($p < 0.05$) (Figure 6.18). However, the specific percentage of needle compression strongly depended on polymer combination and concentration (Figure 6.19). MNA prepared using only PVP as a polymer (F9) exhibited in some cases one of the maximum needle height reductions (36%) and needle deformation (Figures 6.20 and 6.21), representing poor mechanical properties, as previously reported (616,621). In the same way, the F4 prototype showed considerable needle height reduction (42%). In contrast, prototypes formulated with a combination of PVA and PVP (F1-F7) exhibited less compressive behaviours. PVA 9-10 kDa-based MNA did not show any difference between the different polymer proportions. On the other hand, PVA 38-

50 kDa-based prototypes were more resistant to compression, especially when the polymer concentration increased (F7). Specifically, the compression percentage of the F7 prototype was significantly lower than the other MNA ($p < 0.05$), except for the polymer combinations (F5 and F6). The observed reduction in mechanical strength in the F11 prototype can be attributed to the presence of freeze-dried nanoparticles.

Figure 6.18. Needle height before and after compression of each MNA prototype. Height before (colour bars) and after compression (white bars). All results are expressed as mean \pm SD ($n=10$).

Figure 6.19. Height reduction percentage of needles of the different MNA. All results are expressed as mean \pm SD ($n=10$).

This finding agrees with previously reported results where the combination of PVP and PVA increased the mechanical properties of the formulation, attributed to the hydrogen-bond interactions between -OH groups of PVA and C=O groups of PVP (621).

Figure 6.20. F9 needles before compression mechanical test.

Figure 6.21. F9 deformed-needles after compression mechanical test.

Parafilm[®] M was used as a validated artificial skin surrogate for MNA insertion studies, as previously described (619). The results of the insertion studies were in solid agreement with the mechanical strength studies. The insertion capabilities of the MNA prepared using each of nine different formulations is illustrated in Figure 6.22. The results showed that F1-F9 inserted into the third layer of Parafilm[®] M (Figure 6.23). The mean thickness of a Parafilm[®] M layer is $126 \pm 7 \mu\text{m}$, indicating that MNA were inserted up to $378 \mu\text{m}$ of the total height, approximately 83-94% of the needle height, depending on the initial needle height of each MNA. Among them, F7 reached the third layer in

a higher proportion than other prototypes ($p < 0.05$). These values were similar to previous studies focused on the insertion of other polymeric MNA into human skin (622). In contrast, the F11 prototype only penetrated the second layer of Parafilm[®] M, as its needles were shorter than 378 μm .

6.2.4. Drug release study and kinetic model fitting

The use of different polymers to produce MNA leads to different mechanical and chemical properties that influence the drug release process. The different solubility properties and characteristics of the used polymers influenced the release mechanism. Although the release of active ingredients from dissolving MNA is mainly governed by the dissolution of the MNA matrix, other mechanisms are possible, for example, when polymers are insoluble in biological fluids or MNA are coupled with controlled release systems. Different methodologies have been proposed for the *in vitro* assessment of drug release. FDC set-up and the direct dissolution in a sealed beaker method are capable of discriminating release patterns. In this case, the release profiles between the developed formulations are presented in Figure 6.24.

Figure 6.24. Release profiles from B12-MNA: PVP-based prototypes (grey), PVA 9-10 kDa-based prototypes (green), PVA 38-50 kDa prototypes (blue), freeze-dried lipid vesicles-loaded prototype (orange).

In general, the results met the findings obtained in the mechanical tests, as the PVP-based formulation showed a faster drug release than PVA/PVP-based combinations. The PVA 9-10 kDa-based prototype

exhibited a slower release in comparison to the two-polymer combination. The most probable reason for this could be that PVA is less soluble in water than PVP. PVA concentration in F4 formulation is 30% w/w while F1-F3 prototypes contain only 15% w/w of PVA, with a variable proportion of PVP. Nevertheless, the effect of polymer combination was not neglectable in PVA 38-50 kDa/PVP-based formulations. They showed the highest controlled release, probably as a consequence of the high molecular weight of the PVA. However, the increase of PVP proportion up to 20% w/w strengthened the MNA matrix and therefore the controlled release. On the contrary, the addition of the freeze-dried lipid vesicles into the MNA led to soft polymeric structures that delivered their cargo more easily (F11 prototype). In addition, as lipid vesicles present a drug loading limitation in comparison to the free-drug, the B12 dose in F11 was lower and total drug release was achieved.

At the end of the release studies, the PVA 38-50 kDa-based prototypes were the only ones that preserved the polymeric matrix (Figure 6.25), denoting a polymer relaxation/swelling alternative release mechanism to diffusion/dissolution. To confirm this, release data was adjusted to the Korsmeyer-Peppas model, which considers both mechanisms, and the F5-F7 prototypes showed intermediate values of the release exponent “ n ” (0.5-0.85), as expected (Tables S17 and S18, Annex II).

Figure 6.25. PVA 38-50 kDa swelled polymeric matrix after release study.

6.3. Milestone and highlights of chapter 6

Milestone: Eleven MNA loaded with freeze-dried B12-loaded lipid vesicles and free B12 were designed. PVA (9-10 and 38-50 kDa) and PVP were the polymers used in different concentrations to produce the MNA prototypes. Nine of them were successfully produced and characterised.

- **Highlight 6.1:** Lipid vesicle-loaded MNA exhibited shorter needle height as result of increased polymer contraction due to the high proportion of freeze-dried lipid vesicles in the system.
- **Highlight 6.2:** Mechanical strength was evaluated by MNA resistance to compression. The stronger resistance was shown by formulations with high polymer concentration, and PVP-PVA combination.
- **Highlight 6.3:** MNA insertion properties in an artificial skin model were correlated with their mechanical properties, reaching > 276 μm depth in all cases. Moreover, high weight polymers contributed to insertion.
- **Highlight 6.4:** Drug release was strongly dependent on the main polymeric components of the formulation. MNA manufactured with low molecular weight polymers (PVA 9-10 kDa and PVP 40 kDa) completely dissolved in the *in vitro* release test, whereas PVA 38-50 kDa-based MNA maintained the polymeric matrix after the study. In consequence, the processes that govern the release processes are diffusion/dissolution and swelling/relaxation of the polymeric matrix, respectively.

7.1. Materials and methods

7.1.1. Materials

The reagents and materials used are listed in table 7.1.

Table 7.1. Reagents and materials for the *ex vivo* and *in vitro* studies.

Reagent / Material	Information	Supplier
Mili-Q Water	Resistance > 18MΩ TOC < 10 ppb	Millipore (Madrid, Spain)
Methanol	HPLC-grade	VWR (Radnor, PA, USA)
Aluminium mask	-	3M (Madrid, Spain)
Adhesive tape	Tesafilm kristall-klar	Tesa (Hamburg, Germany)
Parafilm M®	-	Bemis (Neenah, WI, USA)
Glass beads	Borosilicate beads Diameter: 1 mm	Sigma-Aldrich (St. Louis, MI, USA)
NaCl	-	Scharlab (Santmenat, Spain)
KCl	-	Scharlab (Santmenat, Spain)
KH₂PO₄	-	Scharlab (Santmenat, Spain)
Na₂HPO₄	-	Scharlab (Santmenat, Spain)
Methylene Blue dye	Powder M _w : 319.85 g/mol	Sigma-Aldrich (St. Louis, MI, USA)
Solid MNA	Needle height: 500 µm	Tyndall UCC (Cork, Ireland)

7.1.2. Methods

Ex vivo and *in vitro* studies were approved by the Ethical Committee of the University of Valencia, under protocol number H1540295606992 (Annex III).

7.1.2.1. Drug distribution within skin layers and stratum corneum depth

Drug penetration through the skin provided by lipid vesicles was evaluated by the tape-stripping technique. The assay was performed using porcine skin samples. Skin was removed from the connective tissues and placed onto a glass slide, with the outside layer facing upwards. An aluminium mask was placed over it, leaving the application area uncovered. 100 µL of each formulation containing lipid vesicles was applied to the delimited application area of skin. The system was then incubated at 32°C

for 2, 4 and 6 h. Each test was performed in triplicate (n=3). After incubation, 20 strips of adhesive tape were applied sequentially to the skin using a roller, according to the standardised procedure, and then removed with a forceps (94). The amount of *stratum corneum* removed was determined by infrared densitometry (SquameScan™ 850A, Hailand electronic GmbH; Wetzlar, Germany) and strips were grouped in different pools, following the sequence: 1, 2, 3-5, 6-10, 11-15, 16-20 (623). The amount of B12 present in each sample was extracted overnight from the strips using a methanol:water mixture (50:50 v/v) as extraction solvent, since it afforded an optimal B12 recovery ratio within the established range (100 ± 20%) (95). Subsequently, B12 was quantified by HPLC with no interference with the analytical method.

7.1.2.2. In vitro drug permeability through the skin

The B12 skin permeability achieved by lipid vesicles and dissolving MNA was evaluated using an FDC set-up (51). The skin permeability obtained by the different nanosystems was compared with the skin permeability of a B12 solution 0.5% (w/v) (79). For those formulations, the experiments were carried out using intact or micro-pored full-thickness porcine skin (59). In the case of dissolving microneedles, skin permeability was assessed using dermatomed porcine skin (600 µm). For this, excised hairless porcine skin was obtained separating it from the cartilage using a scalpel and dermatomising it if necessary (Micro-line Wagnerd dermatome, Aesculap/Braun; Tuttlingen, Germany). The micro-pored skin samples were produced by manually inserting solid MNA with thumb force for 30 sec. Excised intact, micro-pored or dermatomed skin was placed horizontally between donor and receptor chambers, with the *stratum corneum* upwards, of the FDC (effective diffusion area of 1.76 cm²). Specifically for dissolving MNA, the skin was placed onto a foam surface covered with aluminium foil and the donor chamber was strongly attached to the skin using a small amount of cyanoacrylate glue (Loctite®, Henkel; Düsseldorf, Germany). One dissolving MNA was inserted into the skin using a syringe plunger to

apply firm pressure for 30 sec. To secure the insertion of the MNA, they were affixed with Steri-Strip® adhesive bands (3M-Spain; Madrid, Spain) (624). In the case of lipid vesicles, 500 µL of each formulation was added to the donor chamber. The receptor chamber was filled with 12 mL of PBS pH 7.4 (n = 6). Temperature was maintained at 32 ± 1°C throughout the whole experiment. The donor compartment and the sampling port were covered with Parafilm M® to avoid leakage and solvent evaporation. Samples of 200 µL were collected at prefixed times within 12-32 h, depending on the formulation tested and the skin used. At each sampling time, the volume was replaced with pre-warmed PBS to guarantee sink conditions. The released B12 was quantified using the same HPLC analytical method described above, and the cumulative amounts of B12 were plotted versus time. The cumulative amount of drug permeated through the skin was plotted as a function of time. Permeability parameters were calculated by linear regression of the steady state: J_{max} (µg/cm² h), K_p (cm/h) and t_L (h) as a simplification of the Scheuplein diffusion model.

7.1.2.3. Visualisation of micro-pores created by solid MNA

Dye binding studies were performed to visualise the creation of micro-pores by MNA. Microneedle-treated porcine skin was stained with methylene blue dye solution 1% (w/v) for 1 min (503). Then, the insertion site was cleaned with water to remove excess dye. Images were taken by optical microscopy, using a light microscope with a camera (Nikon digital camera DXM1200C, Nikon; Tokyo, Japan). Morphology of solid MNA was also observed by SEM imaging. The insertion depth was determined using an artificial skin model (Chapter 6, 6.1.2.3 subsection) (619).

7.1.2.4. Statistical analysis

All data processing was performed using Microsoft Excel 2016® (Redmond, WA, USA) and SPSS version 22.0® (IBM Corp., NY, USA). Data is expressed as the mean ± standard deviation (SD) unless otherwise stated. As a previous requirement for the statistical tests, normality, homoscedasticity, and sphericity were verified if needed. Normal

distribution for each data set was assessed by the Shapiro-Wilk test. Homogeneity of variances was confirmed by the Levene's test. Variances of the differences between all combinations of related groups were checked by the Mauchly's sphericity test. Statistical analysis was carried out using the T-test for simple comparisons, one-way ANOVA for tests with two variables, and two-way ANOVA for tests with three variables. All ANOVA tests were followed by the proper post hoc test. Specifically, the Games-Howell nonparametric test was used in case of heterogeneity of variances. When the homoscedasticity requirement was met, the Bonferroni or Tukey tests were used when the number of comparisons was low or high, respectively. The Gabriel test was used if the number of samples were different between the groups. Statistical differences were considered significant if p-values were below 5% ($p < 0.05$).

7.2. Results and discussion

7.2.1. Drug distribution within skin layers and *stratum corneum* depth

The *stratum corneum* layers depth in porcine skin was determined by infrared densitometry using a standardised procedure (623). The total thickness obtained was around 20 μm , in accordance with the standard values between 17-28 μm , previously reported by Jacobi et al. (2007) (625). Tape-stripping studies were performed using the most promising formulations according to the afore-presented data: L1, L2, T1d, T2d, E1 and E3. As incubation times, 2 h, 4 h and 6 h were selected, covering the longest time a topical formulation would be maintained on the skin. Furthermore, longer incubation times lead to overhydration of the skin and removal of the whole *stratum corneum* in a single strip (50). The B12 solution 0.5% w/v (S) was used as a reference, since it represents the free diffusion and no enhancing absorption effects are expected from the vehicle. Figures 7.1-7.3 show the progressive B12 penetration in the different layers of the *stratum corneum* at different incubation periods.

Figure 7.1. Penetration profiles of B12 delivered from liposomes (L1 and L2), transferrinsomes (T1d and T2d), ethosomes (E1 and E3), and B12 aqueous solution after 2 h. All results are expressed as mean \pm SD (n=3).

Figure 7.2. Penetration profiles of B12 delivered from liposomes (L1 and L2), transferrinsomes (T1d and T2d), ethosomes (E1 and E3), and B12 aqueous solution after 4 h. All results are expressed as mean \pm SD (n=3).

Figure 7.3. Penetration profiles of B12 delivered from liposomes (L1 and L2), transfersomes (T1d and T2d), ethosomes (E1 and E3), and B12 aqueous solution after 6 h. All results are expressed as mean \pm SD (n=3).

In general, the amounts of B12 detected in the deeper layers of the skin increase as a function of the incubation time, as expected. As shown, the B12 solution presented the highest amount of B12 extracted in the first strip, regardless of the incubation time. Two reasons can explain this fact: the immediate availability of B12 on the skin leading to a quick distribution over the first *stratum corneum* layer, where it is retained; and a deficient cleaning of the skin surface. Concerning the latter, many authors discard this stripe because the inaccuracy of the data is typically high and considered an experimental artefact (91). However, the rest of B12 from the solution did not penetrate the *stratum corneum* nor the deeper skin layers, and only low quantifiable concentrations are detected up to the third strip, which corresponds to 6 μm depth, after 6 h. These findings confirm the inability of B12 to diffuse through intact skin. The E1 ethosome samples presented the lowest quantifiable amounts among all the vesicles tested, probably due to the low B12 load and the gradual release. Samples could have easily been under the detection and quantification limits. The L2 formulation carries less B12 amounts than the other prototypes, consequently showing considerably lower B12 penetration amounts, only

until approximately 15 μm depth (Figure 8c). Nevertheless, L1, T1d, T2d and E3 vesicles allowed B12 to reach the dermis ($>25 \mu\text{m}$). L1 and T2d contained similar B12 doses but after 4 and 6 h of incubation, the transfersomes showed higher permeation rates up to the deepest layers (Figure 8b and 8c). This means that the *stratum corneum* is saturated in B12 at that time point and a diffusion gradient to the deeper layers starts. T1d showed the highest permeation profiles. The penetration results suggest that the transfersome enhancing effect was much higher than the one of liposomes and are in agreement with Abd et al. (2016) (219), who compared the penetration of a hydrophilic drug (caffeine) delivered from liposomes, transfersomes and solution.

B12 has been delivered through the skin using chemical and physical methods by other authors. Yang et al. (2011) studied *in vitro* the effects of chemical enhancers and physical methods in topical administration of B12. Chemical enhancers (ethanol, oleic acid, and propylene glycol) allowed an effective permeability of B12 in comparison with passive diffusion. The permeability enhancement offered by iontophoresis was around 2-fold in comparison to a combination of all enhancers (50% ethanol, 10% oleic acid, and 40% propylene glycol) (626). Although these methods have proven to effectively deliver B12, they present several inconveniences in B12 delivery for atopic dermatitis. For example, they were not able to localise their effects in the epidermis and dermis, leading to an absorption of B12 in systemic circulation, which is unnecessary for psoriatic and atopic dermatitis patients. Also, local skin reactions and poor effectiveness, in combination with hydrophilic molecules, have been reported for chemical enhancers (215).

From the results presented here, it can be concluded that B12 does not diffuse through the *stratum corneum* if formulated in water media, whereas the developed formulations are able to efficiently deliver B12 to the deeper skin layers after 6 h.

7.2.2. In vitro drug permeability through the skin from lipid vesicles

Porcine skin was selected as it is a recommended surrogate of human skin for *in vitro* studies, due to the ethical considerations surrounding human sampling, and the variability associated to human skin samples as a result of differences of age, race, and anatomical donor site (59). Previous studies have determined that among all animal models, porcine skin is the most similar to human skin from the histological point of view (627). In particular, the human forearm and pig ears have a good concordance between the number of cell layers of the *stratum corneum* and whole skin thickness, which have a huge influence on drug permeability flux (628). The results obtained are even more realistic and reliable if we consider that the application area of these formulations in humans is the forearm. Systemic blood concentration parameters of a topically applied drug can be calculated using the skin penetration parameters (629,630). Cumulative amounts of permeated B12 per diffusional area of porcine skin *versus* time are presented in Figures 7.4 and 7.5. The permeability parameters calculated for each formulation and condition are presented in Tables 7.2 and 7.3, as well as the initial concentration of each sample assayed.

Figure 7.4. *In vitro* permeability profiles of B12 delivered from the different lipid vesicle prototypes through intact porcine skin. All results are expressed as mean \pm SD (n=6).

Figure 7.5. *In vitro* permeability profiles of B12 delivered from the different lipid vesicle prototypes through microneedle-treated porcine skin. All results are expressed as mean \pm SD (n=6).

B12 diffusion for 32 h was neglectable when it was administered in an aqueous solution, obtaining drug concentrations in FDC receptor medium below the HPLC quantification limit (Figure 7.4). Moghimipour et al. (2013) reported that it is possible to achieve certain B12 *in vitro* drug permeability from an aqueous solution (631). Nevertheless, they extended the study to 80 h and used a higher concentrated solution, which causes a higher gradient difference between FDC compartments and forces the drug to pass the separating barrier. Also, they used rat skin, which is more permeable than porcine and human skin, and strongly affected by an excessive *stratum corneum* hydration after long exposure to drug-containing solutions (59).

Transdermal absorption of B12 solution can also be improved when containing chemical enhancers like ethanol, as Howe et al. (1967) studied in rat and guinea pig skin (632). The use of chemical enhancers in topical formulations is a strategy that intends to modify the drug barrier function of the skin, or to improve the drug physicochemical properties. However, they

entail certain disadvantages, such as the inability to locate the effects on the *stratum corneum* or skin reactions (irritation, inflammation and erythema) (215).

The developed lipid vesicle formulations notably increased the B12 permeability through the skin, as Figure 7.4 reflects. The calculated fluxes from all formulations tested were as follows: T1d \geq E3 \geq L1 > T2d \geq L2 > S ($p < 0.05$) (Table 7.2). Thus, it can be concluded that the ability to enhance B12 diffusion by lipid vesicles increases with the incorporated dose and vesicle flexibility, while it decreases with vesicle size (633).

Among the formulations containing a similar drug amount, transfersomes and ethosomes showed higher fluxes than conventional liposomes, as expected. This trend has been observed before in several studies (588,634,635). Transfersomes and ethosomes present lower sizes in comparison to liposomes (Chapter 5, 5.1.2 subsection), and particle size has been revealed to be one of the crucial properties to consider for transdermal delivery, since the smaller the particle, the better the transdermal absorption profiles obtained (392). Additionally, different mechanisms have been proposed to explain this behaviour of ultraflexible lipid vesicles. For example: the ethanol-increased solubility of drugs in the vesicles; or their ability to squeeze along the intracellular *stratum corneum* lipids, pushed by the gradient caused by the difference in water content between the moderate dehydrated skin surface and the hydrated viable epidermis (261,636). Other researchers, like Dreier et al. (2016), consider that lipid vesicles are unable to cross intact through the *stratum corneum* layers and they disrupt the compacted intracellular lipids package (259). However, the exact mechanism is not yet completely elucidated.

K_p was calculated correlating the flux to the applied dose, as an efficiency measure of each vesicle (Table 7.2). Again, transfersomes and ethosomes were the most effective formulations. The comparison of the J_{max} and K_p brings the role of the drug cargo that conditions the final vesicle activity to light, since the difference observed in flux between L1-L2

and T1d-T2d is mitigated when the dose is considered. Once again, ultraflexible vesicles offered a significant decrease in the lag time, showing an earlier start of the absorption in comparison to conventional liposomes.

Table 7.2. *In vitro* permeability parameters of B12 delivered from the different lipid vesicle prototypes through intact porcine skin. All results are expressed as mean \pm SD (n=6).

Formulation	Jmax ($\mu\text{g}/\text{cm}^2/\text{h}$)	Kp $\cdot 10^{-7}$ (cm/s)	Lag time (h)	Dose ($\mu\text{g}/\text{mL}$)
Solution (S)	-	-	-	50000
L1	1.00 \pm 0.56	1.26 \pm 0.71	23.87 \pm 0.39	2070
L2	0.44 \pm 0.19	1.61 \pm 0.68	22.91 \pm 1.11	673
T1d	1.73 \pm 0.77	2.41 \pm 1.07	14.51 \pm 1.63	2090
T2d	0.50 \pm 0.11	2.23 \pm 0.45	17.66 \pm 1.55	610
E3	1.51 \pm 0.35	2.08 \pm 0.48	17.53 \pm 2.14	1333

The skin pre-treated with solid MNA led to a further increase of B12 permeability, which was significantly higher than the ones provided by the respective lipid vesicles (Figures 7.4 and 7.5). MNA are considered one of the most promising tools to achieve systemic effects by transdermal delivery of drugs. They are designed as a minimally invasive and painless system that can physically bypass the *stratum corneum* (Figures 7.6 and 7.7) (215,637).

After MNA use, the drug solution provided the highest flux through the skin in comparison to the application of lipid vesicles (Figure 7.5). Nevertheless, it did not correspond to a higher efficiency than the rest of the tested formulations, as a consequence of the great dose administered (Table 7.3). This phenomenon could also be attributed to the vesicles' ability to control the drug released, even when they are present in the skin medium. As stated before, when the barrier function is intact, it is unclear if the drug is released from the formulations, or the vesicles carry the drug to the deeper layers, or they interact with the skin lipids, facilitating drug permeability. However, microneedles remove the barrier function, thus

opening pores of bigger size that could allow the passage of the liposomes, which can therefore still control the release of the drug.

Figure 7.6. Solid microneedles used to create micro-pores in the porcine skin.

Figure 7.7. Needle-like projection visualised by scanning electron microscopy (SEM imaging).

In contrast to what could have been expected, the drug solution showed a similar lag time compared to the flexible vesicles (Table 7.3). Lower lag times after MNA-treatment for all formulations except T1d were observed, although the difference is not significant in this case. The possible reason for this could be that vesicles enhance the delivery of B12 through the skin, which does not happen with the B12 aqueous solution, as previously demonstrated. In the MNA-assisted cases, there are two enhancing effects happening simultaneously: the passage through the microchannels, and the passage through the intact stratum corneum. This

second effect is especially remarkable for transfersomes and ethosomes, where the lag time difference is not significant if MNA are used or not. At this point it should be considered another possible reason, since the microneedles completely perforate the *stratum corneum* as their insertion reaches the deeper skin layers, but the skin sample used also included the epidermis and the dermis. Before the drug can diffuse to the subsequent layer, the previous layer must be saturated with the drug, which is directly related to the partition coefficient for the drug in each medium (50).

Table 7.3. *In vitro* permeability parameters of B12 delivered from the different lipid vesicle prototypes through microneedle-treated porcine skin. All results are expressed as mean \pm SD (n=6).

Formulation	Jmax ($\mu\text{g}/\text{cm}^2/\text{h}$)	Kp $\cdot 10^{-7}$ (cm/s)	Lag time (h)	Dose ($\mu\text{g}/\text{mL}$)
S-MNA	9.23 \pm 1.65	5.12 \pm 0.91	15.66 \pm 0.61	50000
L1-MNA	3.65 \pm 1.22	4.61 \pm 1.53	14.36 \pm 0.45	2070
L2-MNA	1.23 \pm 0.38	4.51 \pm 1.39	11.38 \pm 2.60	673
T1d-MNA	3.38 \pm 0.86	4.27 \pm 1.08	16.27 \pm 0.83	2090
T2d-MNA	1.29 \pm 0.26	4.72 \pm 0.95	13.83 \pm 0.85	610
E3-MNA	2.44 \pm 0.27	3.44 \pm 0.38	16.06 \pm 0.97	1333

The established current posology recommends first shock doses to replenish B12 deposit, followed by maintenance doses. According to the data presented in this work, T1d transfersome formulation presents the highest transdermal flux through the skin, and therefore it can be an optimal candidate for the treatment of this vitamin deficiency. Since the recommended doses are 1 mg/day for 1 week, 1 mg/week for 4-8 weeks and 1 mg/month chronically, T1d formulation could fulfil these requirements using skin areas of around 12, 1.75 and 0.5 cm² respectively, which are perfectly feasible for the design of a transdermal patch. Solid microneedles can be used for pre-treating the skin and to achieve faster and higher cyanocobalamin concentrations, or to reduce the size of the treated skin area. This approach, usually known as “poke and patch”, is clearly delimited

and applicable to the initial stage of the treatment since the time that micro-holes remain open is nowadays under discussion (501,638).

7.2.3. Visualisation of micro-pores created by solid MNA

Methylene blue staining was used to assess the effectiveness of solid MNA to pierce the porcine skin (Figure 7.8). Pictures obtained by optical microscopy were similar to those obtained by Kalluri and Banga (503). Microneedle insertion effectively created microchannels in the artificial skin model (Figure 7.9). First and second skin layers (254 μm) were almost fully drilled (> 90%), which is enough to practically nullify the skin barrier function of the stratum *corneum*. Additionally, around 50% of micro-pores reached 381 μm).

Figure 7.8. Micro-pores on porcine skin after MNA insertion visualised by optical microscopy.

Figure 7.9. Percentage of holes and insertion depth of solid MNA in an Parafilm M[®] skin model. All results are expressed as mean \pm SD (n=3).

7.2.4. In vitro drug absorption through the skin from dissolving MNA

To conduct these studies, porcine skin was dermatomed to 600- μm thickness, reducing the dermis layer which, not being considered as the main limiting factor to the transdermal drug absorption, could slow down the diffusion process. According to the previous results (Chapter 6, section 6.2), F3, F7, F9 and F11 prototypes were selected as representatives of MNA. The differences between them were the insertion capability, dissolving time, and drug loading. PVA 38-58 kDa-based MNA (F7) showed the highest insertion rate and non-complete dissolution of the matrix. F11 prototype (containing freeze-dried lipid vesicles) exhibited the lowest drug loading and needle height.

In vitro permeability profiles are presented in Figures 7.10-7.14, where a two-step process is clearly observed in all cases. It can be explained as a consequence of the transition from solid to hydrogel as a result of swelling and MNA dissolution, which increases the released B12 availability to be permeated through the skin.

Figure 7.10. *In vitro* permeability profiles of B12 delivered from different dissolving MNA prototypes through dermatomed porcine skin. All results are expressed as mean \pm SD (n=4).

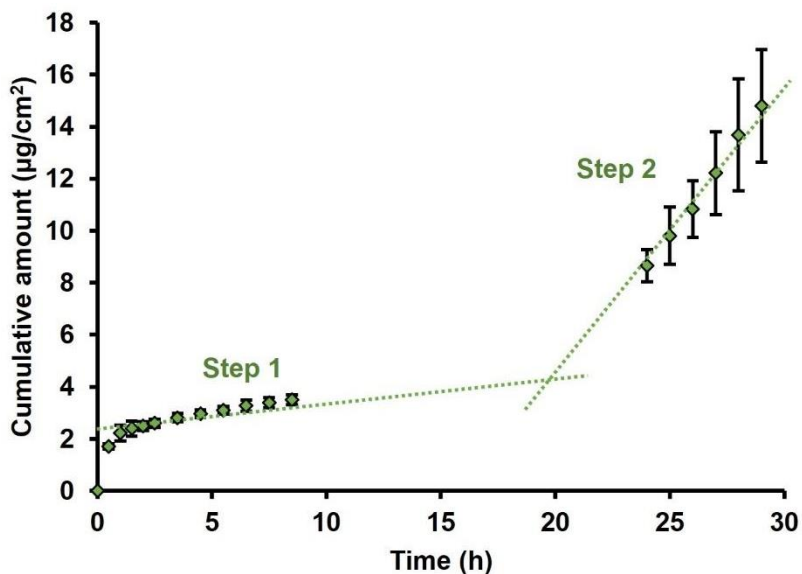

Figure 7.11. *In vitro* permeability profile of B12 from F3 prototype through dermatomed porcine skin. All results are expressed as mean \pm SD (n=4).

Figure 7.12. *In vitro* permeability profile of B12 from F7 prototype through dermatomed porcine skin. All results are expressed as mean \pm SD (n=4).

Figure 7.13. *In vitro* permeability profile of B12 from F9 prototype through dermatomed porcine skin. All results are expressed as mean \pm SD (n=4).

Figure 7.14. *In vitro* permeability profile of B12 from F11 prototype through dermatomed porcine skin. All results are expressed as mean \pm SD (n=4).

The intersection of the two straight lines could be an estimation of the moment when the transition from solid MNA to hydrogel occurs, although it probably takes place gradually. PVP-based prototype (F9) showed the state-transition earlier, as expected after the release studies results (Chapter 6, 6.2.3 subsection). However, the experimental conditions are not similar and, for example, the hydration/swelling of MNA is shorter in the release studies. It should be noted here that the MNA in the release studies was immersed in the fluid, whereas it was placed in the FDC experiments onto the dry side of the skin, not directly in contact with the fluid. Therefore, the different MNA release behaviours can be compared, although not in terms of time. This could be the reason why the F11 prototype, which contains freeze-dried lipid vesicles, needed longer times to show the state-transition process. In addition, insertion depth of the F11 prototype was the most limited, and the hydration fluids coming up from the FDC receptor chamber encountered the MNA later. In this way, the insertion capability of MNA has been revealed as one of the crucial properties in achieving a maximal enhancing effect. *In vitro* permeability parameters are presented in Tables 7.4 and 7.5.

Table 7.4. *J_{max}* of B12 delivered from the different dissolving MNA prototypes through 600- μ m dermatomed porcine skin. S1: MNA dissolution step 1; S2: MNA dissolution step 2. All results are expressed as mean \pm SD (n=4).

MNA	Dose (μ g/mL)	<i>J_{max}</i> (μ g/cm ² /h)		
		Total	S1	S2
F3	1700	0.43 \pm 0.05	0.39 \pm 0.18	1.43 \pm 0.48
F7	2000	4.12 \pm 0.34	0.46 \pm 0.04	10.80 \pm 1.10
F9	1975	1.32 \pm 0.22	0.37 \pm 0.03	2.37 \pm 0.74
F11	500	0.29 \pm 0.02	0.47 \pm 0.07	0.64 \pm 0.04

Table 7.5. *K_p* of B12 delivered from the different dissolving MNA prototypes through 600- μ m dermatomed porcine skin. S1: MNA dissolution step 1; S2: MNA dissolution step 2. All results are expressed as mean \pm SD (n=4).

MNA	Dose (μ g/mL)	<i>K_p</i> · 10 ⁻⁸ (cm/s)		
		Total	S1	S2
F3	1700	7.1 \pm 0.9	Not applicable	23.6 \pm 7.9
F7	2000	55.6 \pm 4.6	Not applicable	145 \pm 14.8
F9	1975	18.6 \pm 3.1	Not applicable	33.4 \pm 10.4
F11	500	16.2 \pm 1.1	Not applicable	35.1 \pm 2.1

Transdermal fluxes were calculated for the global process and the observed steps separately (Table 7.4). S1 and S2 are the slopes obtained by linear regression of the data corresponding to each straight line drawn in the plots (Figures 7.11-7.14).

The calculated fluxes for step 1 were similar for all formulations ($p > 0.05$) since MNA remained in a solid state during the initial hours post-insertion and drug availability was quite similar in all cases. It can be concluded that the limiting step at this phase of the drug diffusion process is the release of the drug from the MNA. However, in step 2, after the experimentally observed solid-hydrogel transition, the calculated fluxes were $F7 > F9 \geq F3 > F11$ ($p < 0.05$). In general, these calculated fluxes meet those obtained when both steps are considered as a single process, because step 2 has a greater impact on the drug absorption process. As mentioned above, insertion depth could be responsible for the difference between F7 and F11 transdermal fluxes, as the higher the insertion depth, the shorter the dermis path to reach the FDC receptor chamber.

K_p was calculated correlating the flux to the applied dose, as an efficiency measure of each MNA (Table 7.5). Nevertheless, this parameter could not be calculated for step 1 as the linear regression of straight lines intercepts with the y-axis before 0 h, offering aberrant values of the calculated parameters. It would also be inadequate, as the dose applied is

freely available for diffusion. B12 doses loaded in F3, F7 and F9 were similar, so the outcome agrees to the findings in transdermal fluxes: $F7 > F9 = F3$. However, F11 efficiency matched the F3 and F9 results, showing again the importance to penetrate the skin with the MNA as much as possible to improve the results. It is worth mentioning that the results of K_p for both dissolving and solid MNA (section 7.2.2) show comparable orders of magnitude, indicating a similar breakdown of the barrier function exerted by the *stratum corneum*.

7.3. Milestone and highlights of chapter 7

Milestone: Lipid vesicles and dissolving MNA allowed B12 penetration and permeability through the skin, which is almost neglectable when drug is administered as an aqueous solution.

- **Highlight 7.1:** B12 penetration was enhanced by the different lipid vesicles. As expected, the amounts of B12 detected in the deeper skin layers increase as a function of the incubation time and the use of ultraflexible vesicles.
- **Highlight 7.2:** B12 permeability results showed the same trend as in the penetration studies, indicating that transfersomes and ethosomes are the most effective vesicles to carry the drug to the dermis, where it can be absorbed to systemic circulation.
- **Highlight 7.3:** B12 permeability through the skin increases when skin is pre-treated with solid MNA. The micro-pores created in the *stratum corneum* almost nullified its barrier function and, consequently, increased notably the permeability rate for highly drug-loaded formulations, equalising the lag times.
- **Highlight 7.4:** B12-loaded dissolving MNA enhanced drug permeability. Absorption profiles showed two differentiated steps. In the first one, the limiting process to drug diffusion is its release from the dosage form. In the second step, the permeability profile changes, and the permeability steady state is achieved, as the arrays are completely dissolved.

- **Highlight 7.5:** Based on the obtained results, it seems that lipid vesicles are the most convenient systems to potentially treat skin disorders, whereas MNA are ideal to achieve a systemic B12 supply.

in a murine model of contact dermatitis**

8.1. Materials and methods

8.1.1. Materials

The reagents and materials used are listed in table 8.1.

Table 8.1. Reagents and materials for the *in vivo* study.

Reagent / Material	Information	Supplier
Oxazolone	> 98% purity	Sigma-Aldrich (St. Louis, MI, USA)
Clobetasol	> 99% purity	Acofarma (Madrid, Spain)
Paraformaldehyde	> 95% purity	Sigma-Aldrich (St. Louis, MI, USA)
Harris' haematoxylin	7 g/L (w/v)	Sigma-Aldrich (St. Louis, MI, USA)
Eosin stain solution	Histological grade	Sigma-Aldrich (St. Louis, MI, USA)
DPX mountant	Histological grade	Sigma-Aldrich (St. Louis, MI, USA)
Bouin's liqueur	Acetic acid 5% Formaldehyde 9% Picric acid 0.9%	Sigma-Aldrich (St. Louis, MI, USA)
Mayer's haematoxylin	1 g/L (w/v)	Sigma-Aldrich (St. Louis, MI, USA)
Ponceau S	-	Sigma-Aldrich (St. Louis, MI, USA)
Phosphomolybdic acid	-	Sigma-Aldrich (St. Louis, MI, USA)
Aniline blue solution	2.5% in acetic acid (2 %)	Sigma-Aldrich (St. Louis, MI, USA)
Dimethylbenzene	> 99% purity	Sigma-Aldrich (St. Louis, MI, USA)
Luminol	Sodium salt	Sigma-Aldrich (St. Louis, MI, USA)

8.1.2. Methods

8.1.2.1. Animals and housing conditions

For the DTH model experiments, a total of 42 BALB/c mice were used. Animals were conditioned to the University of Valencia facilities for 10 days. Afterwards, they were randomly assigned to an experimental group (Table 8.2). All the procedures were in accordance with the principles

of laboratory animal care and approved by the Animal Experimentation and Welfare Ethics Committee (Annex III).

Table 8.2. Experimental groups and number of animals included in each one.

Group/Formulation	Number of animals
Healthy control	6
Oxazolone	6
E blank	6
E3	6
T blank	6
T1d	6
Clobetasol	6

8.1.2.2. Induction of DTH and evaluation of the ear oedema

Oxazolone (OXA) was dissolved in acetone and prepared at final concentrations of 3% and 1% w/v. Abdomen of the animals was shaved (day -1), and one day later they were sensitised by a single percutaneous application of 150 μ L of OXA 3% w/v solution (day 0). On day 5, the hypersensitivity reaction was triggered by applying 10 μ L of OXA 1% w/v solution in each side of the right ear. In this study, 20 μ L of each formulation (10 μ L/side) under research was applied to the right ear after the OXA challenge, and 24 h and 48 h later. Clobetasol propionate dissolved in acetone (0.025 mg/ear) was applied topically and used as a reference drug. Experimental procedure is represented in Figure 8.1. Ear thickness was measured before the OXA challenge and days 6, 7 and 8 using a micrometre (Absolute Digimatic 2[®], Mitutoyo GmbH; Neuss, Germany) (639). Afterwards, animals were euthanised by cervical dislocation and the ears were taken for the histological study.

Figure 8.1. Schematic illustration of DTH model of acute atopic dermatitis.

8.1.2.3. Bioluminescence imaging

For the bioluminescence imaging (BLI), an IVIS Lumina X5 (PerkinElmer; Waltham, MA, USA) was used. Mice were treated with 0.2 mL of luminol (200 mg/kg i.p.; dissolved in PBS) and imaged 30 min after the injection under an anaesthetic protocol (isoflurane inhalation). Total photon emissions were determined at different time points (3, 6 and 24 h) (639).

8.1.2.4. Histopathological study

Skin-pinna biopsies were fixed in paraformaldehyde 4% w/v solution and then embedded in paraffin. Skin sections (5 μ m-thickness) were stained to visualise the skin structures. For haematoxylin and eosin stains, samples were immersed in Harris' haematoxylin solution and then washed to remove the excess dye. Afterwards, they were sequentially treated with a differentiation solution and eosin ethanolic solution (50% v/v). Finally, slides were dehydrated with a sequence of alcohol solutions, mounted using DPX liquid and observed in an optical light microscope (640). Pinna sections were also stained using Masson's trichrome reagent. Briefly, samples were fixed in Bouin's liqueur overnight and then rinsed in two changes of distilled water. Skin sections were sequentially stained with Mayer's haematoxylin, 0.5% w/v hydrochloric acid ethanolic solution (0.5% w/v), acid ponceau, phosphomolybdic acid aqueous solution (1% w/v), aniline blue, and ethyl alcohol (95% w/v). Finally, samples were hyalinised

with dimethylbenzene and sealed with a neutral balsam (641). ImageJ® software (NIH; Bethesda, MD, USA) was used to process the images from histological sections and determine the skin layers thickness.

8.1.2.5. Statistical analysis

All data processing was performed using Microsoft Excel 2016® (Redmond, WA, USA) and SPSS version 22.0® (IBM Corp., NY, USA). Data is expressed as the mean \pm standard deviation (SD) unless otherwise stated. As a previous requirement for the statistical tests, normality, homoscedasticity, and sphericity were verified if needed. Normal distribution for each data set was assessed by the Shapiro-Wilk test. Homogeneity of variances was confirmed by the Levene's test. Variances of the differences between all combinations of related groups were checked by the Mauchly's sphericity test. Statistical analysis was carried out using the T-test for simple comparisons, one-way ANOVA for tests with two variables, and two-way ANOVA for tests with three variables. All ANOVA tests were followed by the proper post hoc test. Specifically, the Games-Howell nonparametric test was used in case of heterogeneity of variances. When the homoscedasticity requirement was met, the Bonferroni or Tukey tests were used when the number of comparisons were low or high, respectively. The Gabriel test was used if the number of samples were different between the groups. Statistical differences were considered significant if p-values were below 5% ($p < 0.05$).

8.2. Results and Discussion

8.2.1. Induction of DTH and evaluation of the ear oedema

Pinna thickness increase has been proposed as a measure of ear skin oedema and vascular permeability (642,643), typically increased in atopic and contact dermatitis processes (639). For these experiments, transfersomes (T1d) and ethosomes (E3) were selected as they showed the best results regarding the B12 penetration and permeability enhancement through the skin (Chapter 7, 7.2.1 and 7.2.2 subsections).

Conventional liposomes and B12 aqueous solutions were omitted as a measure of animal reduction in compliance with the 3 Rs principle (644). Results are presented in Figures 8.2 and 8.3. Pinna thickness was increased in OXA-sensitised groups in comparison to non-sensitised (healthy control group). In addition, ear thickness did not show any increase when animals were treated with clobetasol (1.25 mg/ml w/v), proving the suitability of the model, as the pathological process can be controlled. Specifically, a slight decrease of ear thickness was noticed, probably as a consequence of steroid-induced skin thinning and atrophy (645,646). The non-treated group (OXA group) showed an ear thickness increase of 308 μm after 24 h, which subsided spontaneously over time, as animals were not exposed to the triggering agent again. B12-loaded transfersomes (T1d) significantly reduced (-172 μm) the ear thickness increase in comparison to the untreated group. Blank formulations showed a non-significant oedema reduction when compared to the untreated group. It could be attributed to the emollient properties of the lipid components and the refreshing effect produced by the aqueous vehicle. This confirms the effectiveness of B12 as a nitric oxide scavenger, since nitric oxide-mediated vasodilation, skin blushing, and pruritus are ameliorated (175). Surprisingly, ethosomes (E3) did not produce a satisfactory significant effect. A possible explanation is that the irritation produced by ethanol counteracts the neutralising effects of B12.

Figure 8.2. Ear thickness variation timeline. All results are expressed as mean \pm SD (n=6).

Figure 8.3. Ear thickness variation 24, 48 and 72 h after OXA challenge. All results are expressed as mean \pm SD (n=6). * means statistically significant differences when compared to untreated group (OXA) ($p < 0.05$).

8.2.2. Bioluminescence imaging

The murine DTH model has long been used as a model for dermatitis, and it is well characterised that an inflammatory response via neutrophils, macrophages and T cells is generated (647). Myeloperoxidase (MPO) is an abundant protein present in the granules of neutrophils or polymorphonuclear leukocytes (PMN's). Respiratory burst, through the intervention of NADPH oxidase (Phox) and superoxide dismutase (SDS), produces hydrogen peroxide (H_2O_2) from molecular oxygen (O_2) (648). Finally, MPO catalyses the reaction of this H_2O_2 with chloride anions (Cl^-) to form hypochlorous acid (HOCl), which oxidises the luminol and triggers the chemiluminescence (Figure 8.4) (649). Eventually, MPO can also oxidise the luminol using the superoxide anion ($O_2^{\cdot-}$) in a peroxidase-catalysed oxidation reaction (648,649).

Figure 8.4. Luminol-oxidation BLI via neutrophilic mediation.

Therefore, a BLI assay was conducted to confirm the previous findings, and study whether neutrophils are involved in the pathological process triggered by OXA challenge, since luminol has been used for neutrophils activation and accumulation (650). Results are shown in Figure 8.5. Four groups were studied (OXA, clobetasol, T1d and T blank). Groups treated with ethosomes were discarded due to the poor results obtained in the reduction of ear thickness. The healthy control group was also discarded, since, for this study, the left ear was used as an intraindividual control in each animal.

Sensitisation to OXA generated a significant BLI between challenged (right) and non-challenged (left) ears with a maximum signal after 24 h (OXA group), confirming the existence of a certain leukocyte infiltration. As expected, luminol-induced BLI was completely normalised by clobetasol treatment, since neutrophils and macrophages are typical targets for immune suppression (647). However, contrary to ear oedema studies, T1d also showed a total photon emission attenuation, suggesting an effective mitigation of leukocyte infiltration and its activity in the inflamed area. As previously observed, blank transfersome vesicles (T blank group) reduced the BLI in comparison to the non-treated group, showing yet again a certain degree of effect produced by the aqueous vehicle.

Figure 8.5. Representative images from the luminol-oxidation BLI experiment of the groups of interest.

8.2.3. Histopathological study

A histopathological study was performed to observe the anatomical differences in skin structure between groups treated with transfersomes in comparison to the healthy and non-treated animals. Representative images of eosin-haematoxylin and Masson's stains are presented in Figures 8.6 and 8.7, respectively.

Cellular infiltration as a response to the inflammatory damage after OXA challenge was noticed, like in the BLI assay, which was clearly reverted with T1d treatment (Figure 8.6). Ear thickness measurements based on the digital estimation met those obtained directly in the *in vivo* procedure and showed the same trends in terms of increase reduction when treated with transfersomes (Figure 8.8). However, this skin thickening is not only caused by the oedema -denoted by the skin structure spacing-, as the epidermis and dermis were also thickened in non-treated groups (Figure 8.7).

Figure 8.6. Representative images from the histological sections stained with eosin-haematoxylin of the groups of interest.

Figure 8.7. Representative images from the histological sections stained with Masson's trichrome reagent of the groups of interest.

Figure 8.8. Ear thickness measurements based on the digital estimation of the groups of interest. * means statistically significant differences when compared to untreated group (OXA) ($p < 0.05$) ($n=6$).

8.3. Milestone and highlights of chapter 8

Milestone: Transfersomes (T1d) ameliorated the skin oedema measured as ear thickness in an *in vivo* delayed-type hypersensitivity murine model.

- **Highlight 8.1:** T1d formulation produced a significant reduction of 172 µm in ear thickness increase compared to the untreated control group.
- **Highlight 8.2:** T1d-treated group did not recover the baseline of healthy controls, but the difference between groups was not statistically significant. These results demonstrate that even though T1d could not fully recover the tissue from the pathological process, it contributed to reducing the damage in a considerable manner.
- **Highlight 8.3:** Blank formulations produced a non-significant reduction in ear thickness variation, probably because of the emollient properties of the vesicle-forming lipids and the refreshing ability of the aqueous vehicle. The ear thickness reduction produced by T1d was significantly higher when compared to the blank formulations, thus confirming the effectiveness of T1d.

- **Highlight 8.4:** Leukocyte implication in the pathological process triggered by the OXA challenge was confirmed through BLI assay as an indirect measure of MPO activity. The T1d-treated group showed a similar mitigation to the clobetasol-treated group. Transfersome blank vesicles also produce a partial reduction of cellular infiltration.
- **Highlight 8.5:** Histopathological study of skin sections confirmed the decreased oedema, reduced skin layers thickening, and no increased leukocyte infiltration when contact dermatitis is treated with T1d.

Chapter 9

Conclusions

The most relevant conclusions derived from the data obtained in this work are:

Conclusion 1: B12 can be detected and quantified by HPLC and spectrophotometry UV-vis.

Conclusion 2: Lipid vesicles can be produced and loaded with B12, showing optimal properties for topical and transdermal delivery purposes.

Conclusion 3: B12 and freeze-dried lipid vesicles can be successfully formulated as dissolvable MNA devices that present adequate mechanical and insertion properties to effectively bypass the *stratum corneum* and deliver the drug in the dermis.

Conclusion 4: *Ex vivo* and *in vitro* penetration and permeability of B12 through the skin can be enhanced using advanced transdermal delivery systems: dissolvable MNA > solid MNA-lipid vesicles combination > transfersomes > ethosomes > conventional liposomes > aqueous solution

Conclusion 5: Contact dermatitis and eczema can be ameliorated by the administration of B12-loaded transfersomes which boost the nitric oxide scavenger properties of B12.

Annex III

Experimental protocol authorizations

D. José María Montiel Company, Profesor Contratado Doctor del departamento de Estomatología, y secretario del Comité Ético de Investigación en Humanos de la Comisión de Ética en Investigación Experimental de la Universitat de Valencia,

CERTIFICA:

Que el Comité Ético de Investigación en Humanos, en la reunión celebrada el día 8 de noviembre de 2018, una vez estudiado el proyecto de investigación titulado:

"Estudio de la absorción de activos cosméticos y farmacéuticos a través de piel humana y porcina" número de procedimiento H1540295606992 cuyo responsable es Ana Melero Zaera ha acordado informar favorablemente el mismo dado que se respetan los principios fundamentales establecidos en la Declaración de Helsinki, en el Convenio del Consejo de Europa relativo a los derechos humanos y cumple los requisitos establecidos en la legislación española en el ámbito de la investigación biomédica, la protección de datos de carácter personal y la bioética.

Y para que conste, se firma el presente certificado en Valencia, a doce de noviembre de dos mil dieciocho.

A blue circular stamp of the Universitat de València is positioned to the left of a blue ink signature. The stamp features the university's name in a circular border and a central emblem. The signature is a cursive scribble in blue ink.
