17
18 Abstract

19 Palaeontological studies on exoskeletal disarticulated remains of chondrichthyans
20 have focused on teeth and only less interest has been paid to scales due their limited
21 taxonomic and systematic significance. However, classical works linking the

22 morphology and the function of the squamation in extant sharks suggest that, despite
23 their limited taxonomic value, the study of isolated scales can be a useful tool for
24 palaeoenvironmental and palaeoecological inferences. Following this idea, we have
25 analyzed the fossil record of shark scales from two Middle Triassic sections of the
26 Iberian Chain (Spain), identifying different functional types by means of a
27 morphometric discriminant analysis. From a total of 1136 isolated chondrichthyan
28 scales, 25% were identified as abrasion resistant scales, 62% as drag reduction scales
29 and 13% as scales of generalized functions. The elevated proportion of abrasion
30 resistant scales suggests that this chondrichthyan palaeocommunity was highly
31 dominated by benthic sharks that lived over a hard sea floor. However, one of the
32 stratigraphical levels studied (He-20), presents statistically significant differences from
33 the others, showing a lower percentage of abrasion resistant scales and a larger
34 percentage of drag reduction scales. This level can be linked with punctuated changes in
35 the bathymetry of the basin and changes in the structure of the chondrichthyan
36 community with an increase in benthic-pelagic or pelagic forms. Finally, partial
37 correlation analysis between relative abundances of functional scale types and tooth-
38 based taxa from the same sections provide positive correlation between teeth of
39 *Hybodus* and *Pseudodolatias* and drag reduction scales, and teeth of *Prolatodon* and
40 abrasion strength scales.

42

43 Resumen

44 Los estudios paleontológicos de restos desarticulados de condricios se han
45 centrado en los dientes, no prestando prácticamente interés al estudio de sus escamas

46 debido a su limitada importancia taxonómica y sistemática. Sin embargo, algunos
47 trabajos clásicos que han relacionado su morfología y función en base al estudio de la
48 escamación de tiburones actuales, sugieren que, a pesar de su limitado valor
49 taxonómico, el estudio de las escamas aisladas puede ser una herramienta útil para
50 obtener inferencias paleoambientales y paleoecológicas. Siguiendo estas ideas, se ha
51 analizado el registro fósil de escamas de tiburón de dos secciones del Triásico Medio de
52 la Cordillera Ibérica (España), identificando diferentes tipos funcionales por medio de
53 un análisis morfométrico discriminante. De un total de 1.136 escamas aisladas de
54 condriactos, el 25% de ellas fueron identificadas como escamas resistentes a la abrasión,
55 el 62% como de reducción de la resistencia y el 13% de las escamas como de función
56 generalizada. La elevada proporción de las escalas resistentes a la abrasión sugiere que
57 esta paleocomunidad de condriactos estaba claramente dominada por tiburones
58 bentónicos que habitaban sobre un sustrato rocoso. Sin embargo, uno de los niveles
59 estratigráficos estudiados (He-20), presenta diferencias estadísticamente significativas
60 con los demás, mostrando un porcentaje más bajo de escamas resistentes a la abrasión y
61 un porcentaje mayor de las escamas de reducción de la resistencia. Este nivel se
62 relaciona con cambios puntuales en la batimetría de la cuenca y por lo tanto con
63 cambios en la estructura de la comunidad de condriactos, con un incremento de las
64 formas bento-pelágicas o pelágicas. Por último, el análisis de correlación parcial entre la
65 abundancia relativa de los tipos de escamas funcionales y taxones en basados dientes de
66 las mismas secciones proporcionan una correlación positiva entre los dientes de
67 *Hybodus* y *Pseudodaltias* y escamas de reducción de la resistencia, y diente de
68 *Prolatodon* y escamas de resistencia a la abrasión.

70 **1. Introduction**

71 Due to the cartilaginous nature of the chondrichthyan endoskeleton, the fossil record
72 of this group consists mainly of disarticulated remains such as teeth, scales and fin
73 spines. Within these elements teeth are by far the most informative in terms of
74 taxonomy, systematics or autecology. Most of the extinct species of Chondrichthyes are
75 described on the basis of isolated teeth (see for example monographs of Cappetta, 1987,
76 2012; Ginter *et al.*, 2010 and references therein). In contrast, isolated chondrichthyan
77 scales that commonly occur together with disarticulated teeth, provide limited
78 taxonomic information (especially Mesozoic and Cenozoic taxa, see Reif, 1985a;
79 Karatajute-Talimaa, 1998; Leidner and Thies, 1999; Thies and Leidner, 2011) for three
80 main reasons: the presence of a high morphological diversity of scales in different
81 regions of the body, which has been documented in both extant and fossil specimens
82 (see Reif, 1973, 1974, 1985a); the evolution of some scales of similar, or even, identical
83 morphologies in distantly related species (Muñoz-Chápuli, 1985); and the occurrence of
84 ontogenetic variability (Reif, 1973, 1978). As a consequence, palaeontological studies
85 of disarticulated remains of chondrichthyans have focused on teeth and very little
86 attention has been paid to scales. However we propose that, despite the lack of
87 taxonomic and systematic significance, isolated scales could provide useful information
88 regarding the palaeoecological and palaeoenvironmental conditions. Our proposal is
89 based on the classic works of Reif (1982; 1985a) where the relationship between the
90 shape and function of scales of extant sharks was pointed out. Reif (1982, 1985a)
91 differentiated scales into five different functions: abrasion resistance, defense, drag
92 reduction, bioluminescence and generalized functions, and indentified eight
93 characteristic morphologies associated with these functional types. Abrasion resistant
94 scales are found in demersal sharks, which inhabit rocky or coralline substrates and,
95 generally, in small body regions that are often subject to abrasion in all other sharks,

96 such as the mouth area. Scales of this type are knob-like and smooth (Morphology 1) or
97 strongly ornamented (Morphology 2). Both types very frequently show scratch marks.
98 Defensive scales are common in demersal sharks inhabiting muddy or sandy substrates,
99 and protect them against ectoparasites and the settlement of epibionts. Scales of this
100 functional type are thorn-shaped with the cusps pointing in an upward-posterior
101 direction commonly accompanied by mucus (Morphology 3). Drag reduction scales
102 cover most of the skin surface in fast swimming pelagic sharks. Scales of this functional
103 type have riblets aligned in the direction of fluid flow (Morphology 4). The geometry
104 and arrangement seem to play an important role in the drag reduction although the
105 underlying mechanisms are not well understood yet (e.g. Bechert *et al.*, 2000; Douglas-
106 Dean, 2011; Raschi and Musick, 1986; Reif and Dinkelacker, 1982; Reif, 1985a).
107 Scales associated to bioluminescence have evolved in some mesopelagic sharks,
108 enabling the skin to carry photophores and permitting light to pass between them (Reif,
109 1985b). This functional type is represented by three different morphologies: square-
110 shaped with concave facets (Morphology 5), bristle-shaped (Morphology 6) and thorn-
111 shaped (Morphology 7). Scales with ridges and lateral cusps well developed but shorter
112 than the principal cusp fulfill generalized functions and are found in almost all sharks
113 (Morphology 8). Other functions related to hatching and feeding has been documented
114 for shark scales (Grover, 1974; Reif, 1974; Southall and Sims, 2003), but they are very
115 atypical and have not been found among our material.

116 In this study we firstly characterize the morphology of the five functional types
117 proposed by Reif (1985a) using traditional morphometrics and discriminant analysis.
118 Secondly we assign isolated placoid scales from synchronous levels of two
119 stratigraphical sections (Middle Triassic) of the Iberian Chain (Spain), to these
120 “functional” morphologies. The differential abundance of the functional types allow us

121 to evaluate the structure of the chondrychtyan paleocommunity in terms of the relative
122 dominance of more pelagic or benthic sharks and the properties of the physical
123 environment they inhabited, such as the dominant substrate type, independently of the
124 sedimentology.

125

126 **2. Material provenance**

127 The Middle Triassic (Anisian–Ladinian Muschelkalk) sediments in eastern
128 Iberian Ranges comprise limestones and dolomites that represent epicontinental
129 shallow-marine environments. It is composed of two carbonate units inferred as
130 prograding carbonate ramps, related to shallow marine environments of epicontinental
131 character. The upper Muschelkalk corresponds to the upper carbonate unit -with
132 bioclastic and oolitic limestones, algal buildups and shallowing-upwards marl-limestone
133 sequences- and represents the second and the most important marine transgression of
134 the Middle Triassic in the southeast area of the Iberian range (meridional sector).
135 López-Gómez and Arche (1992) have formally described the Dolomites and Limestones
136 of Cañete Formation for the upper Muschelkalk units of this area.

137 A total of 1136 isolated scales were obtained after the dissolution of carbonate
138 rocks with 10% acetic acid from the Bugarra and Henarejos sections of the Iberian
139 Chain (Spain). Both sections expose dolomitic and limestone sediments of the Cañete
140 Formation. According to López-Gómez and Arche (1992) and López-Gómez *et al.*
141 (1987) it is of Ladinian age based on ammonites, bivalves, foraminiferas and conodonts
142 (see Márquez-Aliaga *et al.*, 2004 and references therein).

143

144

145 The Henarejos section is located 1 km south-east of the village of Henarejos
146 (Province of Cuenca). Ladinian molluscs have been reported by Marquez-Aliaga (1985)
147 and López *et al.* (1987). The Bugarra section is close to the village Bugarra (Province of
148 Valencia). Márquez-Aliaga *et al.* (1984) studied the stratigraphy and the invertebrate
149 paleontological aspects of this section (Fig. 1). All specimens studied herein come from
150 the uppermost member of the dolomites and limestones of the Cañete Formation (see
151 Fig. 1) and are kept in the Museum of Geology of the University of Valencia (MGUV).

152

153 **3. Methodology**

154 In order to characterize the morphologies of each functional type proposed by
155 Reif (1985a) we performed classical morphometric analysis of scales with known
156 functions in extant sharks. Six variables (for explanation see Table 1) were measured on
157 the dorsal surface of the scale crown from specimens figured in Reif (1985a) using
158 ImageJ software. We used a total of 58 scales belonging to the eight scale
159 morphologies. Each morphology was treated as a group. Discriminant analysis was
160 performed to obtain maximum separation among the eight scale morphologies using
161 SPSS Predictive Analytics Software Statistics (PASW) version 18.0. Three variables
162 (LEN, WID and RID) were log-transformed to allow nonlinear combinations between
163 them as sums or subtractions of logarithms in the discriminant functions (see below).
164 Subsequently the fossil specimens were included in the discriminant analysis as
165 unknown specimens and were assigned to one of the morphologies of functional types
166 described by Reif (1985a) based on the similarity of their centroid values. Differential
167 abundances of these functional types were statistically analyzed by Pearson's Chi-
168 square test and Z-test using PASW software with the purpose of detecting differences

169 between stratigraphic levels of the studied sections. Finally, we used Partial Correlation
170 Analysis to compare the relative abundances of scale functional types *vs.* the relative
171 abundances of tooth-based genera in the different stratigraphic levels (dates for tooth
172 occurrences were taken from previous studies, see below). Partial Correlation Analysis
173 allows the study of the relationship between two quantitative variables controlling the
174 possible effect of another one that could mask correlations. Thus, the analysis was
175 repeated four times controlling, in each case, the abundance of a concrete tooth-based
176 genus.

177

178 **4. Results and Discussion**

179 *4.1. Discriminant analysis using scales of extant sharks.* Canonical variate analysis
180 generated six discriminant functions. Coefficients, eigenvalues, proportion of explained
181 variance and canonical correlation are presented in Tables 2 and 3. The first canonical
182 discriminant function explains 53.6 % of the total variance while the second one
183 accounts for 25.8% of the total variance (79.5% cumulative variance). The plot of the
184 two canonical variables illustrates a good separation between the eight morphologies
185 proposed by Reif (1985a) (Fig. 2). The discriminant analysis correctly classifies 100%
186 of original cases, while the percentage of cross-validated grouped cases correctly
187 classifies 93.1 % (i.e. 54 of the 58 scales) (Table 4). In this analysis, scales of
188 morphologies 1, 2, 4 and 7 are the most correctly classified followed by scales of
189 morphology 8. The least correctly classified are the scales of morphologies 3 and 6
190 (Table 3 and 4).

191 These results show that classical morphometric analysis is able to discriminate
192 between the five functional types of chondrichthyan scales proposed by Reif (1985a)

193 using six variables in the discriminant functions. In addition, we also tested other
194 alternatives to the use of the classical morphometric analysis, like geometric
195 morphometrics or Fourier analysis, but the results were not as good as expected. Due to
196 the high morphological variability in scales, it was very difficult to set homologous
197 points in the eight scale morphologies and, therefore, it was not possible to apply
198 geometric morphometrics in an acceptable way. On the other hand, Fourier analysis
199 only takes into account characters reflected in the contour of the scales without
200 considering other features, as for example those related to the ridges, which might be
201 useful to differentiate between groups. Although the results of this method are good,
202 with the percentage of cross-validated grouped cases correctly classified ranging from
203 42.2-80% depending on the number of harmonics and the type of analysis (polar or
204 elliptic), they are not as accurate as those obtained by classical morphometric analysis
205 (Appendix 1 shows results obtained using Fourier analysis).

206

207 *4.2. Discriminant analysis including fossil specimens.* Once the discriminant analysis
208 was established, the 1136 fossil scales from the Henarejos and Bugarra sections were
209 included as unknowns. Following the predictions obtained, fossil scales were assigned
210 to four morphologies belonging to three of Reif's functional types (Fig. 3). 289 fossil
211 specimens (25 %) were identified as abrasion resistant, 705 (62 %) as drag reducing and
212 142 (13 %) were identified as scales of generalized functions. None of the fossil scales
213 were assigned to either bioluminescence type (morphologies 5, 6 and 7) or to the
214 defense type (morphology 3). Abundances of each functional type by section and
215 stratigraphic level are shown in Table 5.

216 When it is taken into consideration that in pelagic sharks scales for abrasion
217 resistance are restricted only to small areas of the body (e.g. surrounding the mouth)

218 representing less than 5% of the total body surface, the high proportion of scales with a
219 protective function against abrasion present in our association become interesting for
220 the interpretation of the data. It could be reasonably related with the presence of a high
221 number of benthic sharks, in which (especially in those living on hard sea floor)
222 abrasion resistant scales cover not only the mouth area but also half of the ventral part
223 of the body and the ventral and anterior areas of the pectoral and pelvic fins (Reif,
224 1985a). Thus, our results indicate that the Middle Triassic chondrichthyan community
225 from the Iberian Chain was dominated by benthic sharks. This suggests a
226 palaeoenvironmental interpretation as an area of shallow marine waters, probably
227 dominated by an abrasive substrate (such as a near-shore hard sea floor environment or
228 some type of lagoon). This interpretation is in accordance with sedimentological data
229 provided by Marquez-Aliaga *et al.* (1984) and López-Gómez *et al.* (1987).

230

231

232 *4.3. Pearson's Chi-square test and Z-test.* Pearson's Chi-square test showed significant
233 differences between levels of the Bugarra and Henarejos sections ($p = 0.000$ Table 5).
234 Z-test allowed us to detect between what levels and in which concrete functional types
235 significant differences occur (Table 6). The test show significant differences between
236 level He-20 and the remaining levels. The percentage of abrasion resistant scales is
237 significantly lower than in all others levels and the percentage of drag reduction scales
238 is significantly higher than in four of the other seven levels (Bu 1-33, Bu 1-26, Bu1-26d
239 and He-18). This suggests a change in the composition of the chondrichthyan
240 community with an increase of the pelagic or benthopelagic forms. In fact the fraction
241 of abrasion resistant scales (5.2%) is close to the expectation for pelagic sharks.
242 Furthermore teeth of supposed benthic taxa (see below) do not occur in this level. These

243 changes could be due to punctuated changes in the bathymetry of the basin related to
244 transgressive-regressive pulses that produce a deepening and a displacement of the
245 coastline where sediments of level He-20 were deposited.

246 Therefore, the analysis of scales allows us to detect changes in shark
247 paleocommunities that indirectly may reflect environmental changes, in bathymetry or
248 the predominant substrate, which could be tested by the sedimentology. Hence our
249 results can be reinforced by future sedimentological works but are valid regardless of
250 them.

251

252

253 *4.4. Correlation with fossil teeth.* Previous studies (Pla *et al.*, 2009; 2013) on isolated
254 teeth from the same samples that the scales of this study identified the following tooth
255 based species: *Palaeobates angustissimus* (Agassiz, 1838), *Pseudodalatias henarejensis*
256 Botella, Plasencia, Márquez-Aliaga, Cuny and Dorka, 2010; *Hybodus bugarensis* Pla,
257 Márquez-Aliaga and Botella, in press; *Prolatodon bucheri* (Cuny, Rieppel and Sander,
258 2001); *Prolatodon contrarius* (Johns, Barnes and Orchard, 1997); *Hybodus plicatilis*
259 Agassiz, 1838; and *Lissodus* aff. *Lepagei* (Fig. 4). Partial correlation analysis between
260 the relative abundances of functional types of scales and abundances of tooth-based taxa
261 at generic level indicates positive correlation between teeth of *Hybodus* and
262 *Pseudodalatias* and drag reduction scales, and teeth of *Prolatodon* and abrasion
263 resistant scales. A negative correlation was present between teeth of *Prolatodon* and
264 drag reduction scales (Table 7). Once more, these results are in agreement with the
265 palaeobiological interpretations based on the tooth morphology (see Pla *et al.*, 2013).
266 Thus, dentitions of *Prolatodon bucheri* and *Prolatodon contrarius* can be identified as
267 belonging to a grasping-crushing feeding strategy (following the terminology of

268 Cappetta, 1986, 1987) with cuspidate anterior teeth and flat lateral teeth. This dental
269 type (present generally in sharks of benthic habits) corresponds to a trophic adaptation
270 for durophagy and indicates crustaceans, ostracods, or shelled invertebrates such as
271 gastropods and bivalves as the preferred prey. In consequence, the obtained positive
272 correlation between *Prolatodon* and abrasion strength scales is expected. In addition,
273 *Pseudodalatias* exhibited a cutting-clutching dentition extremely similar to those of
274 some extant neoselachian Dalatiidae (Gray, 1851). The feeding preferences of dalatiids
275 consist of “parasitic” bites excising portions of flesh from large-size oceanic animals,
276 including other sharks, marine mammals and bony fishes (Gasparini and Sazima, 1996;
277 Soto and Mincarone, 2001; Heithaus, 2004; Heithaus and Vaudo, 2012). This trophic
278 behavior is favoured by sharks with a benthic-pelagic swimming mode that look for prey
279 in the water column. Therefore, the positive correlation between teeth of *Pseudodalatias*
280 and drag reduction scales was also predictable. Finally, the multicuspidate teeth of
281 hybodonts are considered to be adapted for a “grasping and swallowing” strategy
282 (clutching- or tearing-type *sensu* Cappetta, 1987) that could include prey such as other
283 small fishes, soft-bodied animals and arthropods. This strategy is present in both pelagic
284 (as in some *Isurus*) and benthic sharks (such as Scyliorhinidae or Squatinidae, Cappetta,
285 1987). The positive correlation found between *Hybodus* teeth, which almost all belong
286 to the species *H. plicatilis*, and scales of the drag reduction type indicate that this
287 widespread shark – known from Germany (Agassiz, 1843), Switzerland (Meyer, 1849;
288 Rieppel, 1981; Scheinpflug, 1984) Spain (Pla *et al.*, 2009; 2013) and Saudi Arabia
289 (Vickers *et al.*, 1999) was a benthic-pelagic to pelagic swimmer.

290 It is important to remark, that the good statistical correlation found between the
291 abrasion resistant scales and durophag tooth-based taxa (that putatively belonging to
292 benthic sharks), and the high correlation between cutting teeth and drag reduction

293 scales that could belong to more pelagic shark, strongly supports the idea that no
294 taphonomic bias affect significantly the relative abundance of the different type scales,
295 and hence our final results.

296

297 **5. Conclusions**

298 Classical morphometric analysis has been able to discriminate among the eight
299 morphologies, included in five functional types, of chondrichthyan scales proposed by
300 Reif (1985a). A high percentage of cross-validated grouped cases were correctly
301 classified (93.1 %). This strongly supports a high possibility of correct identification
302 when the discriminant functions are applied to isolated fossil scales.

303 A total number of 1136 isolated chondrichthyan scales were collected from two
304 Middle Triassic sections (Henarejos and Bugarra) of the Iberian Chain. They were
305 included in the discriminant analysis resulting in the identification of 25% as abrasion
306 resistant, 62% as drag reduction and 13 % as scales of generalized functions. Neither the
307 scales of the bioluminescent nor the defensive type defined by Reif (1985a) could be
308 recognized. The elevated proportion of abrasion resistant scales indicates that the
309 chondrichthyan palaeocommunity from the Middle Triassic of the Iberian Chain was
310 dominated by sharks adapted to a benthic life-style. This is in agreement with
311 palaeobiological interpretations provided by previous analyses of isolated
312 chondrichthyan teeth from the same sections (Pla *et al.*, 2013) which show that in terms
313 of diversity, the chondrichtyan fauna was dominated by durophagous sharks most of
314 them with grasping-crushing dentitions. Dentitions of this type imply feeding
315 preferences including crustaceans, ostracods and shelled invertebrates (gastropods and
316 bivalves), and they are currently present in sharks which live in close relationship with
317 the substrate bottom looking for their prey. Thus, in our opinion, the high percentage of

318 abrasion resistant scales (i.e. of benthic sharks) could be likely related with a
319 palaeoenvironment of shallow marine waters, mostly dominated by a rough substrate,
320 such as a rocky shore platform. Our dates are in agreement with sedimentological and
321 paleontological studies in the area (see e.g. Márquez-Aliaga *et al.*, 1984; Márquez-
322 Aliaga and López-Gómez, 1989; López-Gómez and Arche, 1992).

323 The statistical analyses results in differences between level He-20 (Henarejos
324 section) and all other levels concerning the relative abundance of the functional types of
325 scales. The percentage of the abrasion resistant type in this single level is significantly
326 lower but that of drag reduction scales significantly higher. This can be linked with
327 punctuated changes in the bathymetry of the basin -related to transgressive-regressive
328 pulses- and changes in the structure of the chondrichthyan community with an increase
329 in the pelagic forms. Finally, the partial correlation analysis between the relative
330 abundances of functional types of scales and tooth-based taxa allowed the detection of a
331 positive correlation between teeth of *Hybodus* and *Pseudodolatias* and drag reduction
332 scales, and teeth of *Prolatodon* and scales of the abrasion resistant type.

333 In summary, our analyses show that, despite their limited taxonomic value, isolated
334 scales can be a useful tool for palaeoenvironmental and palaeoecological inferences of
335 the chondrichthyan palaeocommunity. The good concordance of the results obtained
336 from morphometric discriminant analysis of chondrichthyan scales from the Middle
337 Triassic of the Iberian Chains with inferences based on isolated teeth and
338 sedimentological data suggest that this methodology can be extrapolated for studies in
339 other localities.

 687 scales. Significant correlations are identified with a single asterisk (A: Control variable
 688 *Prolatodon*; B: Control variable *Lissodus*; C: Control variable *Pseudodalatias*; D:
 689 Control variable *Hybodus*).

690 Tabla 7. Resultados del análisis de correlación parcial entre los dientes fósiles y los
 691 tipos funcionales de escamas. Las correlaciones significativas se presentan con un
 692 asterisco (A: Variable control *Prolatodon*; B: Variable control *Lissodus*; C: Variable
 693 control *Pseudodalatias*; D: Variable control *Hybodus*).

694

A			Teeth genera		
			<i>Hybodus</i>	<i>Pseudodalatias</i>	<i>Lissodus</i>
Functional type	Abrasion strength	Correlation	-0,142	0,214	-0,171
		Significance	0,761	0,645	0,714
	Drag reduction	Correlation	-0,080	0,182	-0,225
		Significance	0,864	0,697	0,628
	Generalized functions	Correlation	0,358	-0,622	0,607
		Significance	0,431	0,136	0,148

695

B			Teeth genera		
			<i>Hybodus</i>	<i>Pseudodalatias</i>	<i>Polyacrodus</i>
Functional type	Abrasion strength	Correlation	-0,515	-0,269	0,775*
		Significance	0,237	0,560	0,041*
Functional type	Drag	Correlation	0,431	0,451	-0,864*

type	reduction	Significance	0,335	0,310	0,012*

700 Appendix 1. Percentages of original and cross-validated grouped cases correctly
701 classified obtained using Fourier analysis (Polar and elliptical) with different number of
702 harmonics (20, 40, 60 and 100).

703 Apéndice 1. Porcentajes de casos originales y por validación cruzada clasificados
704 correctamente usando Análisis de Fourier (Polar y elíptico) con diferente número de
705 armónicos (20, 40, 60 y 100).

Original cases				
Number of harmonics	20	40	60	100
Polar Fourier Analysis	82 %	88 %	88 %	87 %
Elliptical Fourier Analysis	80 %	88 %	86 %	53,3 %

706

707

Cross-validated cases				
Number of harmonics	20	40	60	100
Polar Fourier Analysis	76 %	70 %	72 %	80 %
Elliptical Fourier Analysis	64 %	68 %	66 %	42,2 %
